BACTERIOLOGY OF ACUTE RHEUMATIC FEVER WITH AN EXPERIMENTAL BASIS IN ANIMALS FOR VACCINE THERAPY*

B. J. Clawson, M.D.
Department of Pathology, University of Minnesota
Minneapolis

TWO aspects of the bacteriology of acute rheumatic fever are considered in this paper: (1) the evidence that acute rheumatic fever is due to a streptococcus (not a specific strain); and (2) experiments in animals suggesting a possible basis for vaccine therapy against these streptococci.

It is now generally agreed that acute rheumatic fever is an infectious disease, but opinion is still divided as to whether the disease is of streptococcic origin or is produced by an unknown virus.

The evidence that rheumatic fever is caused by a diplococcus (streptococcus) has recently become fairly convincing. The following facts support this idea: (1) streptococci can be cultured from the blood and joint fluids in a relatively high percentage of cases; (2) agglutinins against streptococci are commonly found in the blood of patients with rheumatic fever; (3) bacterial endocarditis, which is known to be of streptococcic origin, cannot be sharply separated clinically or anatomically from acute rheumatic endocarditis; (4) streptococcic lesions produced experimentally in animals (endocarditis, Aschoff nodules, subcutaneous rheumatic nodules) bear a close resemblance to corresponding lesions in man; (5) there is a definite similarity in the allergic reactions to streptococci in persons having acute rheumatic fever and in animals made hypersensitive to streptococci experimentally.

It is to be observed in Table 1 that the organism commonly recovered by the various workers from the blood, joints, and pericardial exudate before death or at the time of necropsy from patients with acute rheumatic fever or chorea is a diplococcus or a streptococcus. The frequency with which this organism is found appears to be too great to be due to secondary invasion.

The following workers have made attempts to culture the blood, joints, or pericardial exudates: Tribolet and Coyon,[1] Apert,[2] Westphal, Wassermann and Malkoff,[3] Poynton and Paine,[4] Philipp,[5] Loeb,[6] Beaton and Walker,[7] Beattie,[8] Camisca,[9] Beattie and Yates,[10] Collins,[11] Rosenow,[12] Herry,[13] La Fetra,[14] Morse and Floyd,[15] Swift and Kinsella,[16] Quigley,[17] Zinsser and Yu,[18] Suranyi and Forro,[19] Nye and Seegal,[20] and Cecil.[21] All but three of these reported finding diplococci or streptococci in from 8 to 83.5 per cent of the cases examined. Six hundred and thirty-three cases were cultured with an average of 60 per cent of positive results.

The organisms do not conform to a specific strain in respect to the action on the blood agar plate, the fermentation test, or the immunological reactions. Most of the strains reported appear to have been in what is now called the *Streptococcus viridans* group, but typical hemolytic strains in smaller numbers have been reported. Strains inactive on the blood agar plate have been mentioned. It has been our experience that these strains after a few transfers on blood agar produce the green zone about the colony. The lack of conformity to a single strain is illustrated by agglutinating and cross agglutinating strains from acute rheumatic fever and subacute bacterial endocarditis against their respective sera. The majority of the organisms from both sources fall into a common group. The remainder appear to be an irregular group made up of strains

TABLE I

BACTERIAL FINDINGS IN ACUTE RHEUMATIC FEVER

Authors	Time	Organism	No. of cases	Percentage positive
Triboulet & Coyon	1897	Diplococcus	6	100
Triboulet & Coyon	1898	Diplococcus	11	100
Apert	1898	Diplococcus	2	50
Westphal, Wassermann & Malkoff	1899	Streptococcus	1	100
Poynton & Paine	1900	Diplococcus	8	100
Philipp	1903		31	0
Loeb	1908	Diplococcus	45	17.5
Beaton & Walker	1903	Diplococcus	15	100
Walker & Ryffel	1908	Diplococcus	3	0
Camisa	1910	Streptococcus	9	67
Beattie & Yates	1913	Streptococcus	106	45
Collins	1913	Streptococcus	2	100
Rosenow	1913	Streptococcus	8	87.5
Rosenow	1914	Streptococcus	7	57
Herry	1914	Diplococcus	60	71.6
La Fetra	1915	Streptococcus	2	100
Morse & Floyd	1916	Streptococcus	26	8
Swift & Kinsella	1917	Streptococcus	58	12
Quigley	1918	Streptococcus	21	50
Zinsser & Yu	1928	Streptococcus	4	100
Suranyi & Forro	1928	Streptococcus	25	68
Cecil	1928	Streptococcus	29	31
Nye & Seegal	1929		25	0
Cecil	1929	Streptococcus	29	83.9
Clawson	1930	Streptococcus	100	50
Total			633	60

which, as a rule, are agglutinated only with homologous sera.

The conclusions to be drawn from the findings of the various workers on the basis of morphologic, cultural, and immunological characteristics is that the group of streptococci isolated from cases of rheumatic fever cannot be considered a specific one, but that it represents a heterogeneous group, generally green-producers on blood agar, with moderately low virulence.

Relatively little work has been done to determine the incidence of immune bodies in the sera of rheumatic fever patients. In the sera of seven of twelve cases, Tunnicliff found agglutinins for streptococci. Swift and Kinsella found no agglutinins in five patients tested. I have tested the sera of twenty-five patients having acute rheumatic fever and in twenty of these agglutinins have been present in dilutions ranging from 1:50 to 1:800 (Table 2).

The distinction between subacute bacterial endocarditis and rheumatic endocarditis is often difficult to make clinically. Streptococci may be cultured from the blood in both cases, but much more readily from bacterial endocarditis because of the greater number of organisms in the blood stream. A consideration of the method of culturing may be helpful in deciding whether the organisms cultured are from a case of acute rheumatic fever or from a case of bacterial endocarditis. Growth in liquid media may be from either, but, if several colonies develop from a blood agar plate, when the blood used is from the patient, the evidence is strong that the case is what is called clinically bacterial endocarditis.

In endocarditis immediately associated with rheumatic fever (rheumatic endocarditis, simple verrucous endocarditis), the heart valves on gross examination show small, smooth, globular nodules at the points of contact of the leaflets. The chief lesions found on the valves in subacute bacterial endocarditis are soft villous vegetations. The consistence and size of these vegetations make it easily possible for particles to break loose into the blood stream and produce the embolic processes so commonly found in subacute bac-

TABLE II

FREQUENCY OF IMMUNE BODIES IN PATIENT'S SERUM

Author	No. examined	Positive	Negative
Tunnicliff	12	7	5
Swift and Kinsella	5	—	1
Clawson	25	20	5

terial endocarditis, but vegetations of the rheumatic type are found mixed in with the large soft vegetations in at least two-thirds of the cases of subacute bacterial endocarditis. This frequency of association of the two lesions seems to be too great to be explained on a basis of double infection.

Microscopically the lesions of the valves in acute rheumatic endocarditis show the inflammation beginning within the substance of the leaflet. The inflammatory reaction is polyblastic in character. The cells are round and spindle shaped with abundant cytoplasm. The valve tissue beneath the thrombus in cases of subacute bacterial endocarditis shows a reaction similar to that found in the valves in acute rheumatic endocarditis. This gross and microscopic similarity in the vegetations and in the cellular reaction strongly suggests a similar etiologic agent in the two kinds of endocarditis. The subacute bacterial type has been definitely proved to be of streptococcic origin.

In considering whether the streptococcus may be the etiologic agent in producing acute rheumatic fever, much importance rests upon whether lesions similar to human rheumatic lesions can be produced experimentally in animals. Many workers have produced valvular endocarditis experimentally by injecting streptococci. Apparently, in most cases the lesions are large and simulate the bacterial type, but vegetations characteristic of the rheumatic type are not infrequently encountered. Experimental nodular lesions structurally similar to the so-called Aschoff bodies have been produced in the myocardium and the subcutaneous tissues by Coombs, Miller and Kettle, Jackson, and me. By injecting streptococci into rabbits and monkeys I was able to produce an arteritis which appears similar to that described by Pappenheimer and Von Glahn as being specific for acute rheumatic fever.

The experiments and observations of Swift and Birkhaug and my recent experiments have shown that there is a marked similarity in the hypersensitiveness (allergy) in patients having acute rheumatic fever and in animals made hypersensitive experimentally to streptococci.

The facts that streptococci are recovered from the blood and joints in so high a percentage of cases of acute rheumatic fever, that agglutinins for streptococci are so frequently found in the blood in cases of acute rheumatic fever, that the lesions in acute rheumatic fever are so similar to those in subacute bacterial endocarditis (which is known to be due to streptococci), that lesions similar to those found in acute rheumatic fever can be produced in animals by injecting streptococci, and that there is a definite similarity in the hypersensitiveness to streptococci strongly suggest that the most probable cause of acute rheumatic fever is the streptococcus. It remains to be seen what can be done in the way of treatment by combating these organisms.

In recent experiments I have been able, by giving intravenous vaccinations, to desensitize animals made hypersensitive to streptococci experimentally and prevent the development of subcutaneous nodular lesions, which are the nearest approach to rheumatic lesions in animals yet produced. Subcutaneous injections of vaccines do not protect the animals. Since the hypersensitiveness to streptococci in patients with acute rheumatic fever appears to be similar to the hypersensitiveness in these animals, it seems possible that patients with acute rheumatic fever might be desensitized and the further progress of lesions prevented by receiving intravenous streptococcic vaccinations.

CONCLUSIONS

1. Acute rheumatic fever appears to be due to an infection with streptococci.
2. These streptococci do not appear to be a specific strain.
3. Streptococcic rheumatoid lesions in animals made hypersensitive to streptococci can be prevented by intravenous vaccination.
4. This method of vaccination may be indicated in patients with acute rheumatic fever, since such patients are hypersensitive to streptococci.

AMBRUSTER, RUSBY—AND ERGOT

For almost three years one Howard W. Ambruster, an importer of ergot, with the advice of H. H. Rusby, has charged vociferously, repeatedly, frantically, that the fluidextract of ergot U. S. P. of American manufacture, was grossly substandard. Controlled scientific evidence from creditable sources to sustain the charges has not been presented. In innumerable circular letters, in broadsides, in statements to the press and wherever he can get a hearing, Mr. Ambruster asserts there is a conspiracy on the part of the American Medical Association and of the Food, Drug and Insecticide Administration of the U. S. Department of Agriculture to approve substandard drugs. Not only has the American Medical Association as an organization been attacked, but various officials have been subjected to Ambruster's diatribes. Moreover, the American Pharmaceutical Association, the office of the Secretary of the Treasury, many pharmaceutic houses, office of the Secretary of Agriculture, the U. S. P. Revision Committee and others have been included. The campaign which Ambruster has waged and continues to wage would command admiration if there appeared to be any sincerely altruistic motive for it. But there appears to be no evidence to substantiate his charges. Both the Council on Pharmacy and Chemistry and the Journal of the American Medical Association have reported on two different occasions that there was no evidence that fluidextract of ergot U. S. P. as found on the market should not be used with confidence by American physicians. Last June the Committee on Agriculture of the United States Senate held hearings on the Ambruster charges. The evidence permitted to go into the record was not limited to the "indictment." Members of the medical profession and officials of the American Medical Association were grossly accused by Ambruster and Rusby. While a definite report has not been made by the Senate Committee as a whole, the impression created on the technical members of the committee and apparently shared by most of the nontechnical members was fairly well summarized by comments made by Senators Copeland and Hatfield in the closing days of the hearing. Senator Copeland held that no evidence has been presented to show that the quality of fluidextract of ergot was a menace to mothers in childbirth and that he had not heard any testimony to show that the government officials had been lax in their enforcement of the law. (Jour. A. M. A., September 6, 1930, p. 722.)

RHEUMATIC FEVER IN CHILDHOOD*

Henry F. Helmholz, M.D.,
Rochester, Minnesota

RHEUMATIC fever in childhood is an acute infectious disease, probably caused by a streptococcus and characterized by proliferative and exudative changes in the joints, serous membranes, heart, blood vessels and skin. The so-called rheumatic cycle includes tonsillitis, arthritis, carditis, and chorea. The disease, named for its most striking symptoms, is serious largely because of its crippling effect on the heart. Although the involvement of the joints is acute and severe, they usually become completely normal after an attack.

ETIOLOGY

According to practically all statistics, the disease is more common in the poorer classes in the United States as well as in Europe. The incidence of the disease has decreased with improvement in general hygienic conditions. Rheumatic fever makes up from 3 to 7 per cent of the medical diseases observed in children's hospitals.

Season.—In the United States and in Europe the majority of cases are noted in the winter and spring. Relapses also are most common at these seasons. In England, on the other hand, more cases are noted in the autumn. This difference in incidence never has been adequately explained.

Familial relationship.—There appears to be definite familial relationship to the disease. Whether this is due to environment or to infection carried from parent to child, or whether there is a real predisposition is difficult to determine.

Age.—The disease is seen only infrequently in children less than five or six years of age. In a series of 2,051 cases, Curschmann and Eckstein found that the disease had been acquired before the fifteenth year in 7.6 per cent, and of these children 80 per cent had carditis.

PATHOLOGY

The pathologic changes in the joints are not typical. Characteristic changes of rheumatic fever are found in the myocardium in the so-called Aschoff body, a small group of lymphocytes with a central mass of multinucleo-epitheloid cells. In recent years it has been shown that not only the heart, pericardium, myocardium, and endocardium are often affected but also the entire circulatory system, both pulmonary and systemic. The lesions of the heart probably are embolic in nature, the endocardial lesions resulting over areas of necrosis due to small emboli in the vessels of the valves. Recently, the interstitial changes of the mitral valves involving the entire leaflet have been emphasized. The changes in chorea probably are vascular.

SYMPTOMS

There is usually an antecedent upper respiratory tract infection, at times strikingly associated with fatigue, followed at a varying interval by high fever, marked perspiration, increased pulse rate and arthritis. Pain, tenderness, redness, and swelling in one or more joints appear, with later involvement of others, principally of the large joints. There may be a single cycle or a series of cycles of fever and arthritis involving numerous joints.

Characteristic arthritis disappears without permanent injury to joints. In certain cases the upper respiratory tract infection and the arthritis alone are manifested. In a great many cases, however, there also is evidence of involvement of the heart. In 95 per cent of Swift's series transitory changes of the heart according to weekly electrocardiograms were shown.

Carditis.—As the involvement of the heart is the most serious aspect of rheumatic fever, it is important to consider each case of rheumatic fever as possibly carditis until it has been proved definitely that the heart is not involved. The presence of Aschoff bodies in practically all cases of rheumatic fever demonstrates that myocardial changes are constant. The incidence of endocarditis is lower and that of pericarditis is still lower.

Since functional murmurs occur in childhood in practically all febrile conditions, it is at times extremely difficult to determine organic disease of the heart. It is practically never possible to make a diagnosis of endocarditis from a single examination of the heart alone. I have found the following points useful in the differential diagnosis: the functional murmur tends to be basal, but may be present at the apex in maximal intensity; it is usually rather harsh, representing a fraying out of the first sound without a sharp beginning but generally with a sharp end-point. The murmur tends to be louder in the recumbent position and to disappear on exercise. The murmur of endocarditis in its early stages is heard as a soft blowing, with a sharp beginning and a sharp end-point, and it is distinct from the first sound. The murmur is the same whether the patient is lying or standing and becomes more intense with increased action of the heart. In exceptional cases I have noted functional murmurs gradually assume the characteristics of an organic murmur.

---

*From the Section on Pediatrics, The Mayo Clinic, Rochester, Minnesota. Read before the Minnesota State Medical Association, Duluth, July 15, 1930.

A sufficient number of cases of acute endocarditis of the mitral valves has been described to demonstrate that the lesion may heal completely. Amberg and Willius have described such cases seen at The Mayo Clinic.

Pericarditis is usually manifested by a to-and-fro murmur, generally heard best along the left border close to the sternum.

Nodules.—The presence of rheumatic nodules seems to vary considerably from year to year. It has been my experience that during certain periods rheumatic nodules are very common; at other times they are not found, or are only present in small numbers. They are usually found on the back of the head or around the large and small joints of the feet, hands, legs and arms. By flexion and tightening of the skin over the joints the nodules usually appear about 0.5 cm. in diameter, although they may be as large as 1 cm. These nodules are helpful in the diagnosis of rheumatic fever and are of serious prognostic import if present in large numbers and in new crops.

Chorea.—Chorea should definitely be considered as part of rheumatic fever and not as a complication occurring as a later manifestation of the disease. Not infrequently it is a primary mode of onset.

Growing pains.—This symptom as evidence of rheumatic fever is extremely difficult to evaluate. The relation of growing pains to the disease has been over-emphasized by so many observers that indefinite pains in the lower extremities have been considered as a definite manifestation of rheumatic fever. In my experience, a great many cases of growing pains are the result of flat feet, and can probably be explained on this basis. If an acute infection of the upper respiratory tract is followed by indefinite pains in the lower extremities the possibility of rheumatic fever should be considered.

DIAGNOSIS

Polyarthritis that responds to treatment with salicylates and disappears without residue justifies a diagnosis of rheumatic fever. The occurrence of subcutaneous nodules, cardiac involvement, and chorea, alone or in any combination, is diagnostic of the disease.

The differential diagnosis must take into account polyarthritis disappearing without residue that occasionally is seen in serum disease, polyarthritis of gonorrheal origin, and polyarthritis of lupus erythematosus disseminata. Polyarthritis occasionally is seen with chronic ulcerative colitis. Acute rheumatic fever of the spine may be taken for meningitis because of the positive Kernig's sign and stiffness of the neck. The absence of meningeal irritation on spinal puncture, however, tends to make the diagnosis clear. Osteomyelitis may occasionally present diagnostic difficulties.

PROGNOSIS

The death rate from acute rheumatic fever is between 3 and 5 per cent. The prognosis becomes increasingly bad with each relapse because of the increasing frequency of endocarditis, myocarditis and pericarditis. In cases of obliterative pericarditis the prognosis is especially poor, although recent operative procedures have improved it remarkably. The presence of fever and an increased leukocyte count, even after the disappearance of other symptoms, usually means persistent infection. Elimination of foci of infection and a period of rest sufficiently long to give the cardiac lesions an opportunity to heal improve the prognosis. Kaiser, in a recent report on the effect of tonsillectomy on the incidence of rheumatic fever, stated that removal of the tonsils definitely decreased the incidence of rheumatic fever and carditis but that the number of cases of chorea had increased.

TREATMENT

It is well to emphasize the beneficial effect, almost forgotten, of salicylates given in large doses of from 4 to 6 gm. a day during the acute stage, watching carefully for evidence of toxicity, nausea, vomiting, and nephritis. Smaller doses of the drug may be continued for from one to two weeks after the disappearance of symptoms.

Removal of all foci of infection, tonsils in particular, should be carried out as early as possible after the disappearance of acute symptoms. This should be followed by a long period of rest, varying from six months to a year, in an attempt to effect cure of the carditis and chorea. As it is not possible to determine the changes in the heart during life, such protracted periods of rest seem to be justified.

SUMMARY

Rheumatic fever in childhood may be monosymptomatic or may show a few or all of the manifestations of the so-called rheumatic cycle. Complicating disorders of the heart are very common and constitute the serious danger of the infection. All patients with rheumatic fever should have foci of infection removed, and should be given a period of from one to two months of restricted regimen. Patients with carditis or chorea should be kept at absolute rest for periods of from six months to a year, after which the normal mode of life may be resumed gradually.

INCREASED POTENCY OF VIOSTEROL PREPARATIONS

The Wisconsin Alumni Research Foundation informed the Council on Pharmacy and Chemistry that the accumulated clinical experience with viosterol has shown that better results in the treatment of rickets are secured when a dosage of Vitamin D is used larger than that originally recommended and that the maximum limits of safety as to the amount of Vitamin D that can be used has now been more definitely determined than was the case when preparations of viosterol were first put on the market. Instead of increasing the dosage of the present products, the Foundation and its licensees determined to increase the potency of the preparations. It was decided to increase the potency of viosterol in oil so that instead of having 100 times the Vitamin D potency of a standard cod liver oil as determined on rats by the Steenbock line test, it shall have 250 times that potency, and, provided the Council should agree, to increase the potency of cod liver oil with Viosterol so that instead of having 5 times the potency of a standard cod liver oil as determined on rats by the Steenbock line test, it shall have 10 times that potency. The Foundation announced that these preparations of increased potency would be placed on the market beginning with October first. The Council on Pharmacy and Chemistry announces that it has accepted the changes of potency determined on by the Foundation and has changed the name of viosterol in oil 100 D to viosterol in oil 250 D and the name of cod liver oil with viosterol 5 D to cod liver oil with viosterol 10 D and has continued the acceptance of the viosterol preparations already accepted, under the new names. (Jour. A. M. A., October 4, 1930, p. 1021.)

RHEUMATIC CARDITIS*

Max H. Hoffman, M.D.,
Saint Paul

IT IS generally accepted that acute rheumatic fever is an infection due to some type of streptococcus modified by predisposing factors the nature of which we know very little.

The older term, acute articular rheumatism, stressed the joint manifestations. The more recently accepted designation—acute rheumatic fever—indicates its more general distribution. Even this name is not altogether correct, as there has accumulated much evidence to show the necessity of considering this disease to be of a subacute or chronic nature.

It is essentially a perivascular disease distributed throughout the body in a manner that has been likened to the wide-spread distribution of tuberculosis and syphilis. The various tissues of the heart are especially prone to involvement, and the resulting carditis is a very essential part of the picture. This form of heart disease must not be considered as being secondary to, or resulting from joint inflammation. It often appears without the presence or history of any arthritis. Although the joint lesions are the most dramatic in their manifestations, the heart lesion is most important, and may persist for many years after the arthritis has disappeared.

Heart disease ranks first in the list of those diseases producing death. Next to hypertension comes acute rheumatic fever as the agent responsible for heart fatalities. It has been estimated that rheumatic carditis contributes over 20 per cent of all cardiac deaths. The importance of this figure is further added to by the fact that most of this group are infected early in life, and the age group of these deaths is much earlier than the group caused by hypertension and arteriosclerosis.

It is not my purpose to discuss in detail the etiological factors concerned in the production of this disease. The relationship of foci of infection and rheumatic carditis has not been fully established. Hölsti's investigations have shown that the inflamed tonsil in this disease may be merely a part of the acute rheumatic fever, and not the source of the infection.

There also appears to be some hereditary or constitutional factors that predispose to the infection. Repeatedly, cases of rheumatic carditis are found in different generations of the same family. This has occurred sufficiently often to impress students of this disease with the possibility of there being an inherited predisposition.

PATHOLOGY

In the acute stages the disease is a septicemia. The lesions are formed around the blood vessels throughout the body, but especially in the joints, heart, nervous tissues and skin. The histology of the pathological change is essentially the same, no matter what tissue is involved. In the heart the acute lesion consists of a necrotic center with a zone of leukocytic infiltration and cell proliferation. Many round cells are present, and larger multinucleated cells are prominent. These lesions are all located around and in the walls of the smaller blood vessels of the coronary circulation, and bear the name Aschoff nodules.

Some degree of heart involvement is found in almost every case. Proliferative and exudative lesions are found in the endocardium, myocardium and pericardium. These tissues may be involved separately or together. It is not certain whether these changes are produced by the direct action of the bacteria or the toxins of the disease, or whether they are of the nature of an allergic reaction. Active lesions may be present for as many as thirty years after the disappearance of the joint inflammation. Scars in the myocardium are not frequently found, indicating the transient nature of most of these lesions.

The conduction system is especially liable to injury. Although this is difficult to demonstrate histologically, it is well shown by electrocardiograph studies. Poyton, who has studied this disease for over twenty-five years, considers the myocardial lesion to be the most frequent and most important change in children. It is usually overlooked for the reason that it often produces no clinical evidence.

Although the myocardial changes are the most important in the acute stages, it is the valvular disease that produces the severe crippling in later life. The valves most commonly involved are the mitral and aortic. Stenosis of the mitral valve is the typical valvular deformity found in this condition.

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, July 15, 1930.

For many years it has been held that the valvulitis occurred from the blood in the heart chambers, the inflammation extending from the surface inwardly. The more recent conception considers the infection starting as an interstitial valvulitis, and extending toward the surface. This belief has been further substantiated by the discovery of capillaries in the heart valves in adults. It was thought that these capillaries, normally present in the fetus, disappeared at birth. Deep valvulitis, without superficial erosion, is frequently found, and especially often in the valves of the right heart. Superficial valvulitis rarely occurs alone. We should consider the valvular lesion not as an endocarditis, but as an interstitial valvulitis.

The early valvular lesion consists of proliferation and exudation, with the edema playing an important part. The contact of the swollen leaflets at the margin of closure, very likely contributes to the superficial changes that take place in the approximating edges of the valves. In some individuals the proliferative changes are more marked than the exudative. This type of change is capable of producing the more severe kind of valvular deformities. Although valvular disease may be present at the period of acute inflammation, its evident signs may not appear until contraction of the scar occurs.

Pericarditis is a fairly frequent occurrence. The subpericardial tissue is richly supplied with blood vessels, and it is around and in these blood vessels that the inflammation takes place. If the process is sufficiently intense, the pericardial surface will be involved, and the characteristic rub will be produced. Severe congestion in the subpericardial capillaries may cause a rupture through into the pericardial sac, and a hemorrhagic pericarditis results. Exudation of fluid may take place, and often a large effusion is present.

The lesions in the heart take place in and around the smaller ramifications of the coronary arteries. Occasionally some of the larger blood vessels are involved, and anginal pains may be produced.

There may be some question as to the advisability of including the subject of subacute bacterial endocarditis in the discussion of rheumatic carditis. The exact relationship between these two forms of heart disease is not entirely clear. They present several points of similarity that would suggest that they are essentially the same disease. The valvular lesion, however, is very different. In the subacute disease the valve leaflets are injured, with the production of a soft, friable vegetative growth that breaks off and produces the embolic phenomena that are so characteristic of this type of valvulitis. The lesions in acute rheumatic fever are smooth and firm, and cannot be dislodged. Subacute bacterial endocarditis is a fatal disease, and about one-half the cases that come to autopsy show some of the typical rheumatic lesions, in addition to the vegetative changes found in the valves. Many of these patients have a history of previous joint lesions, subcutaneous nodes, and rheumatic carditis. In both conditions the blood will yield cultures of the same type of streptococcus. This would suggest that subacute bacterial endocarditis is nothing more than a very severe form of rheumatic heart disease, brought about by an unusually virulent type of streptococcus, or occurring in an individual who is extremely sensitive to this infection. It is important to make the differentiation, because of the difference in prognosis.

THE ONSET OF RHEUMATIC CARDITIS

The development of rheumatic carditis cannot be described as occurring in any typical manner. It is an essential part of the disease and has no time relationship to the appearance of the other lesions.

In children there may be present no findings other than the mild joint pains, growing pains, or slight chorea, which may be so insignificant as to be completely overlooked. In adults the joint and throat inflammation is usually quite definite, and demands a great deal of attention. The subcutaneous nodes, when they are present, are usually accompanied by heart involvement.

Leukocytosis and fever are the two main findings indicating activity. Often the valvular lesion does not present the diagnostic physical findings, for some time after the acute symptoms have disappeared. In fact, it is usually impossible during the acute stage to definitely say that a valvulitis is present.

Even very slight evidence of the presence of acute rheumatic fever, such as very minor joint pains, an occasional subcutaneous node, low grade fever and leukocytosis, should make one suspect the presence of a heart lesion.

It must be emphasized that there are a number of cases of rheumatic carditis that do not at any time present any other symptoms of acute rheumatic fever. This group comprises from 20 to 30 per cent of all the cases of rheumatic heart disease.

PHYSICAL FINDINGS AND DIAGNOSES

There is often a great deal of difficulty in determining the presence of the heart lesion. This is especially true when only the myocardium is involved. There are several observations that can be made, aside from the heart examination. Any increase in temperature or leukocytosis in a patient showing joint symptoms, but without the involvement of new joints, points toward the onset of a carditis. The presence of subcutaneous nodes usually indicates that the heart has been damaged. An unusually rapid pulse, out of proportion to the temperature, frequently means a myocardial injury.

The physical signs of early myocardial and endocardial involvement are usually not very definite. Dilatation can occasionally be made out by noting the shifting of the left border to the outside of the left mid-clavicular line. When the conduction system is involved, various degrees of heart block may be present, although it requires the use of an electrocardiograph to determine the less severe changes in the conduction time, and the other myocardial lesions. In the more severe degrees of heart block, dropped beat can be made out.

During auscultation, muffling of the apical tones is said to indicate edema of the valves. Frequently a soft systolic murmur is heard along the left sternal border. Libman believes this is a very early sign of valvular involvement. Ordinarily not much significance is attached to a murmur of this type, but when it occurs during the course of a rheumatic fever it may indicate cardiac damage, especially if it is accompanied by an accentuated second pulmonic tone.

When the pericardium is involved, and the surface becomes roughened, a characteristic sound is produced. This is usually a to-and-fro murmur, rather rough, and heard close to the ear. When the visceral and parietal pericardium become adherent this rub disappears. The disappearance and reappearance of the pericardial murmur indicates that activity is still present, and it is a valuable sign. In practically every case the presence of pericarditis means also some involvement of the other tissues of the heart.

Precordial pain and cutaneous hypersensitiveness often indicate the presence of a myocardial lesion. Swift has shown that over 70 per cent of the cases with arthritis and carditis had precordial pain, and that 90 per cent of the cases with subcutaneous nodules had pain and hyperesthesia.

He also observed that those patients with precordial distress had, as a rule, a more severe form of heart disease. The heart muscle itself does not respond to stimuli with pain, but the blood vessels and especially the adventitia, are capable of producing pain and hyperesthesia when they are inflamed. In acute rheumatic fever the lesion is located in and around the adventitia. If the large coronary vessels are involved the distress may be very similar to that which occurs in coronary sclerosis. The pericardial inflammation also produces precordial pain. Sometimes this is very severe, and often occurs with respiration.

THERAPY

Unfortunately we have no specific treatment for rheumatic carditis. From our knowledge of this disease, it appears that we must look to the immunologist for help in perfecting a desensitizing or immunizing agent.

Drugs do not play a prominent part in the treatment of this condition. There is no good evidence to show that salicylates have any effect in preventing the heart lesion or modifying the course of the carditis. There is no question but that it is of great value in relieving the patient of the distress due to the joint inflammation and fever. However, the remarkable symptomatic relief that it frequently produces, often gives the physician a false sense of security, as it masks the onset of the heart lesion.

Digitalis is frequently given as soon as a heart lesion is suspected. This form of therapy is certainly not indicated unless there are definite signs of heart failure. It is toxic to the heart muscle which is already suffering from the effect of the toxin of rheumatic fever.

The nature of the pathological change that takes place in this disease indicates the necessity for resting the heart until it has completely recovered from the effect of the acute process. As long as the pulse is rapid there is a good possibility that activity is still present. Fever, even though it be of a very low grade, is significant, and, along with leukocytosis, indicates that the infection is still present. These three conditions should be watched carefully. It is difficult to say just how long rest should be enforced. Four to six weeks after all signs of activity have left should be a minimum period of quiet. Usually the heart will completely recover from the myocardial lesion if given enough time. Too early or too vigorous exertion may cause serious damage.

It has been suggested that these heart patients should be treated in a manner similar to the treatment of a tuberculous individual—rest during the acute periods, followed by graduated exercise, sunlight and fresh air, until the patient is able to again become useful and active. Much work along these lines is now being done, especially in England, with rather encouraging results.

Lastly there arises the question—what part do foci of infection play in this disease, and how should they be attacked? As a matter of principle, all areas of infection should be removed. Infected teeth and sinuses do not seem to have a close relationship to this disease. Inflammation of the tonsils and acute rheumatic fever occur together so frequently that it would seem that there is something more than a mere coincidence. However, it has not been definitely shown that removal of tonsils prevents the rheumatic carditis or changes the course of the disease very markedly. It is generally agreed that infected tonsils should be removed, but it should not be done during the acute period of the disease, but rather after the fever has subsided.

A guarded prognosis should be given in every case, remembering that evidence of serious heart trouble may appear only many months after the first attack of arthritis; that this is, frequently, a very chronic type of disease, accompanied by many relapses or reinfections; and that with each exacerbation the heart lesion may become progressively worse. It should also be borne in mind that rheumatic carditis frequently occurs without any of the other obvious signs of acute rheumatic fever. Complete rest for a sufficient length of time, followed by graduated exercise, is the most important therapeutic measure.

THE PROTEAN PATHOLOGICAL MANIFESTATIONS OF RHEUMATIC FEVER*

EDWIN L. GARDNER, M.D.
Minneapolis

THE modern conception of the pathology of rheumatic fever is rapidly undergoing a change. The most evident clinical symptoms of the disease and the studies of the pathologists of twenty-five years ago had directed our attention toward the joint signs and the circulatory "complications." Aschoff in 1904 described in detail the histopathology of the minute inflammatory nodules of the ventricular myocardium, and Clawson has recently critically reviewed our present knowledge of the "Aschoff nodule" as observed in man and similar lesions as produced experimentally in animals. During the past decade, but especially during the past five years, there has been a renewed interest in the study of the histogenesis of this lesion which was formerly considered specific for this disease.

The "Aschoff nodule" is usually found in close relation to small arterioles or capillaries, and represents the reaction of connective tissue to the virus or its toxic products. The "typical" nodule varies somewhat depending upon the tissue involved, the virulence of the infection and the resistance of the patient. A constitutional factor has been suggested. In general the tissues show both a proliferative and an exudative reaction of varying degrees; it may be essentially proliferative with the formation of multinuclear giant cells resembling other types of granulomata, or it may be essentially exudative. The latter may be mostly lymphocytic and plasma cells, or at the other extreme be essentially polymorphonuclear with microscopic abscess formation, but suppurative lesions as a rule do not occur because of the low virulence of the rheumatic infection.

A lesion close to a serous membrane such as the epicardium, pleura or joint synovial membrane is likely to excite an exudative process in the serous cavity.

The late lesion or reparative scar is just as variable. The specificity of the "Aschoff nodule" has more recently been questioned, since an atypical proliferative nodule may be found in some "non-rheumatic" conditions where the virulence is low. It has been described for the myocardium in scarlet fever, pneumonia, subacute bacterial endocarditis, meningococcic infections, erysipelas and in general where the infection is due to relatively avirulent sterptococci.

The relation of allergy to the production of some of the tissue reactions, similar to that which is believed to occur in tuberculosis, is at the present time a very attractive field for study. It is difficult to explain all of the immune reactions of this disease without assuming such an hypothesis. Some experimental studies afford considerable evidence in favor of this viewpoint.

In another paper of this symposium the cardiac lesions of rheumatic fever have been discussed but an additional study of all of the known lesions affords us a better conception of the pathological process.

A. Lesions involving the larger arteries.

This is supposedly by the path of the vasa vasorium.

(1) The aorta.

Klotz in 1912 described a non-suppurative mesaortitis and also an involvement of the adventitia. Intimal changes may also occur, often similar to the endocardial lesions of the auricle. Typical Aschoff nodules are sometimes present near the nutrient vessels and in the adventitia. During the healing there may be patchy destruction of muscle fibres in the media due to interference with the blood supply. A patchy aortitis results which is probably in the more extreme cases a cause of dissecting aneurysms. The large areas of dilatation which occur in syphilic aortitis generally do not occur because there is not the widespread destruction in rheumatic disease of the aorta.

It is well to remember that not all cases of aortitis are syphilitic.

(2) The main pulmonary arteries may show lesions similar to those in the aorta, namely a proliferative mesarteritis near the nutrient vessel with secondary changes in the adventitia and intima. Thrombi may form in the injured vessels which may cause additional damage such as pul-

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, July 15, 1930.

monary atelectasis and compression endarteritis. The symptom-complex known as Ayerza's disease may be the end-results of such an arteritis.

(3) Lesions of other large arteries have been described in patients dying a cardiac death, but the evidence leaves a doubt as to the real etiology in many of these reports.

B. Lesions primarily affecting the smaller arterioles and capillaries.

As a rule the moderate size arteries show little or no demonstrable lesion. Only arterioles the size of an arterial nutrient vessel or smaller seem to be involved.

(1) The myocardium, valve leaflets, subendocardium, and subendothelial capillaries of the pericardium may be affected. These lesions have been discussed by others in this symposium.

(2) Pulmonary Aschoff nodules involving the interstitial tissue occasionally occur. This may be followed by an exudative process into the alveoli with some of the signs of an atypical pneumonia. It does not become a suppurative or an essentially exudative process such as clinicians see in lobar or post-influenzal pneumonias. The patients are often so free from symptoms and signs that true rheumatic pneumonia is overlooked. It is rarely in itself fatal, but there may be crippling sequelæ due to scar formation.

Rheumatic pneumonia must be differentiated from a lobar or bronchial pneumonia, complicating acute rehumatic fever or its later complications, and it should not be confused with the embolic process observed in sub-acute bacterial endocarditis. Compression of the lower part of the left lung associated with pericardial effusion may show many of the signs of a pneumonia.

Pleuritis accompanies pneumonia or pericarditis, or it may be the only demonstrable chest lesion. It may be fibrinous or may be accompanied by an effusion. Many of the "wet" pleurisies diagnosed in the past as tuberculous were probably due to "masked rheumatic infections" in the broader sense of the term.

(3) Rheumatic involvement of the other internal organs has not so commonly been observed, but now and then many of the organs may show areas of rheumatic proliferation or typical nodules. Clinical kidney damage is rare, but occasionally lesions of the glomerular vessels have been described in necropsy material. In chorea there are commonly cerebral perivascular lesions resembling the rheumatic nodule.

(4) The typical rheumatic tissue reaction has commonly been found in the joints, subcutaneous tissues, tendons, muscles and other connective tissues. In general it seems that all capillaries of a certain size may be affected. There has been considerable speculation as to the relation of the rheumatic infection to chronic arterial disease.

In conclusion we may state that the pathological process in acute rheumatic fever is a non-suppurative, proliferative or exudative lesion about the smaller arterioles and capillaries throughout the body. The symptoms and signs differ depending upon the number and distribution of these lesions, but most commonly our attention is directed toward those organs where the disturbance is clinically most easily demonstrable.

THE NON-ARTICULAR FORMS OF RHEUMATIC FEVER*

HARRY OERTING, M.D.
Saint Paul

AN IMPORTANT feature of rheumatic fever, and one that cannot be overstressed, is that inflammation about the joints is not necessarily an accompaniment of the infection. These non-articular manifestations are just as much a part of the infection as is the arthritis and they must be recognized as such and treated accordingly. Although the various clinical manifestations of the disease are quite different the underlying pathological lesion is the same.

The non-articular forms of rheumatic fever cannot be discussed as a whole, because they are different clinical entities and although it is possible to have one or more of these different manifestations present at the same time, usually, however, they appear singly.

Chorea frequently occurs without any other of the so-called rheumatic manifestations in children. One striking feature of chorea is the frequency with which one or another of the symptoms and signs of rheumatic fever may appear as isolated evidence of activity. It may be many years before the child shows enough different manifestations to establish the true nature of the disease. The symptoms though difficult to describe are never forgotten when once seen nor do they offer any difficulties to the diagnostician except in their rarer forms. According to the severity we recognize three forms: the mild, the severe, and that associated with delirium. It should be remembered that choreiform movements are increased by excitement or obstruction, entirely cease during sleep whether natural or induced by drugs, and that neither sensibility nor usually reflex activity is affected.

Several of the non-articular forms of rheumatic fever are capable of producing a great deal of pain, which is the complaint that brings the patient to his physician. Muscular rheumatism, fibrositis, or myalgia, terms that are used interchangeably, is an extremely common form of ailment. It is a condition of muscular fibrositis, due to microbic toxic absorption; to anoxemia through faulty local blood supply; or colloidoclastic tissue changes. It occurs frequently as a sequel to tonsillitis and is peculiarly likely to develop after exposure to cold or dampness, excessive fatigue, and any factors tending to reduce the body reserves. The condition may involve any muscle or group of muscles, but usually the lumbar muscles (lumbago), the muscles of the chest (pleurodynia), and the cervical muscles (rheumatic torticollis) are the ones affected. The fundamental diagnostic points are diffuse tenderness of the involved muscles; the pain is distinctly related to muscular contraction, and is absent or greatly relieved when the muscle is at rest. Except in the case of pleurodynia the amount of pain present is dependent chiefly upon the voluntary use of the muscle group affected. In pleurodynia the movement is obligatory, but, in general, spontaneous pain is relatively slight or wholly absent, though local tenderness may be extreme. The presence of tenderness over the muscles involved and the prompt pain response to movement make the diagnosis.

Care must be taken lest a persisting torticollis due to organic disease be mistaken for myalgia, which is ordinarily of but a few days duration. Pleurodynia must never be accepted as the diagnosis without a careful examination of the heart, lungs, and pleura. A strikingly similar pain may be present with intercostal neuralgia, but tenderness over the nerve and pain regardless of motion and definite points of maximal tenderness should clarify the diagnosis. The precursor pain of herpes zoster must also be kept in mind.

Neuritis often accompanies muscular rheumatism as a primary involvement or reflection of adjacent inflammatory processes. Like muscular rheumatism, neuritis usually follows exposure to cold, dampness, and excessive fatigue. Neuritis most commonly involves the sciatic and brachial nerves and is often hard to distinguish from myalgia, but the pain follows more closely the course of the nerve, is aching in character and the loss of function of the regions supplied may be more complete. Both muscular rheumatism and brachial neuritis must be differentiated from cervical rib, tumor of the neck, glands in the axillæ, aneurysm of the subclavian artery, spinal tumor and caries of the cervical vertebræ.

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, July 15, 1930.

Subcutaneous nodes or nodules are one of the most characteristic and diagnostic lesions found in rheumatic fever. They are small, hard, tender masses, deep under the skin and frequently cause the patient a great deal of pain. The lesions may come anywhere on the body but are usually on the lower extremities. There may be only a few nodules present or there may be many, but even one or two typical lesions are sufficient for a diagnosis. The nodules are not constant and vary from day to day or may disappear for considerable periods of time.

Pleurisy is not an unexpected accompaniment of severe polyarthritis, but it must be remembered that it may be an isolated manifestation of rheumatic fever. Although the condition is rare, cases are encountered where pleurisy precedes any other signs of infection by months. This makes it extremely difficult at times to decide whether a patient is suffering from rheumatic fever or tuberculosis. Effusion is the exception rather than the rule in this type of pleurisy and the pleuritic rub tends to come and go.

Erythema nodosum, a very acute type of inflammatory infection of the skin, is characterized by the formation of various sized, roundish, more or less elevated erythematous nodes and is attended by varying degrees of systemic disturbance. The lesions are seen for the most part on the tibial surfaces and may often be limited to these regions. Not infrequently, however, other regions are involved, more especially the arms and forearms. They are rarely present in great numbers, usually from two or three to thirty being found. They begin as a rule as deep seated nodules, rapidly growing larger and becoming elevated. In size they vary from that of a cherry to a hen's egg, are rounded or oval, tender and painful, and have a glistening tense look. They are of a bright red color that merges gradually into that of the normal skin. Later the color changes to a purple and then the various color changes of an ordinary bruise. As they develop they become soft and semi-fluctuating but they never suppurate. The condition should not be confused with the lesions of erythema induratum, which are thought to be of a tuberculous nature. Another skin lesion related in some respects to erythema nodosum is that which is described as erythema multiformi. Many authors believe these two skin diseases to be closely related.

The above mentioned conditions, with the exception of chorea, are usually found in adults. In children various mild pains are frequently present that are commonly referred to as growing pains. Without question many of these children are suffering with rheumatic fever. Many investigators consider them to have the same significance as severe arthritis and that they are to be considered as indication of active rheumatic infection likely to implicate the heart. Without doubt in many instances the so-called growing pains do not indicate active rheumatic fever. The differentiation is difficult to make, but in a child with other evidence of infection they must be viewed with concern.

In conclusion it is well to emphasize again that the non-articular forms of rheumatic fever are just as important as the articular forms and challenge our diagnostic acumen.

ACUTE BOWEL OBSTRUCTION*

Owen H. Wangensteen, M.D.
Minneapolis

THE outstanding consideration in the study of acute intestinal obstruction is the appalling mortality. Forty-one years ago, before the German Congress of Internists convened at Wiesbaden, Professor Curschmann deplored the bad results of surgical treatment and stated that medical measures gave fully as large a number of recoveries. The mortality with the conservative non-operative treatment in his clinic was 65 per cent. A year earlier at a meeting of the American Association of Physicians and Surgeons in this country, this subject was extensively discussed by Reginald Fitz and Nicholas Senn. It was brought out that the surgical mortality in the treatment of intestinal obstruction was 69 per cent. A large number of recognized authorities participated in the discussion and it was the consensus of opinion that after conservative measures had been tried for two days without success recourse should be had to surgery.

Today it is universally conceded that operation should be done for the relief of acute bowel obstruction as soon as the diagnosis can be made. Despite this general acknowledgment, cases come to operation almost as late as when it was uniformly agreed that conservative measures should be tried for two days.

Present day surgical results, though somewhat better than those obtained in the surgery of acute intestinal obstruction at the dawn of the era of abdominal surgery, exhibit no such striking improvement as can be boasted in the surgical treatment of most other acute abdominal catastrophes. Statistics from our municipal hospitals where cases of acute bowel obstruction are seen in large numbers indicate that the mortality is almost as great today as it was forty-two years ago.

C. Jeff Miller has recently published a study of the cases of acute intestinal obstruction admitted to the Charity Hospital and Touro Infirmary in New Orleans. In the five year period, immediately preceding his report, there were 343 cases with 207 deaths, a mortality of 60.9 per cent. In 1900, Gibson reviewed from various hospitals 1,000 cases of intestinal obstruction that had been subjected to surgery, with a mortality of 43.2 per cent. VanBeuren and Smith in 1925 published a collected report on 1,089 operations performed since 1900 with a mortality of 41.8 per cent.

Why do 40 to 60 per cent of patients operated on for acute intestinal obstruction die? Why does this high mortality still continue?

During the half century that has passed since the aggression of surgeons into the domain of the abdomen, strides of great consequence have been made in treatment; witness the improvement of results in the surgical treatment of acute appendicitis, acute perforations of the stomach and duodenum and other abdominal disasters of an acute nature. Today, death following an operation for acute appendicitis is synonymous with delay in the recognition of the ailment or procrastination in advising surgery. Similarly, death from perforations of duodenal or gastric ulcers signifies that an unreasonable length of time has intervened between the onset of the symptoms and the intervention of the surgeon. In 1922, Barber and Stewart reported twenty-four operations for perforated duodenal ulcer with two deaths; in the lethal cases surgical interference had been delayed for more than twenty-four hours. Today the mortality varies directly with the number of hours lost between the occurrence of the catastrophe and the closure of the perforation.

Why has not the remarkable improvement attending the surgery of other acute abdominal lesions extended to intestinal obstruction?

The results of a large number of experimental investigations have indicated that the absorption of a toxin producing profound and overwhelming effects on the organism is in large measure responsible for the mortality of the disease. Though recently several investigators have obtained results at variance with this explanation, many clinicians have been quick to seize upon the toxic factor, finding in this refuge some sol-ace for their misgivings and a satisfactory account for their poor results.

---

*From the Department of Surgery, University of Minnesota. Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 15, 1930.

The fact remains, however, that all statistical studies indicate that there is a rising mortality in intestinal obstruction commensurate with delay in arriving at the diagnosis and procrastination in advising surgery. In cases operated upon at an early hour after the onset of symptoms, the mortality compares favorably with the surgery of other abdominal emergencies. In any number of papers on obstruction of the intestine, the difference in risk between those cases that come to operation early and those submitted to surgical intervention late is striking.

THE RISING MORTALITY OF DELAY (TUTTLE)

From onset of symptoms to operation	Total	Deaths	Per Cent
Under 6 hours	13	0	0.0
Under 12 hours	25	1	4.0
Under 24 hours	39	7	15.4
Under 48 hours	50	9	18.0
Under 3 days	70	17	24.3
Under 4 days	84	26	30.9
Under 6 days	99	37	37.4
All cases	128	53	41.3

In a consecutive series of 283 cases operated by Flint and reported by him in 1921, the mortality of operation for all cases of intestinal obstruction was only 15.6 per cent. Recently Holden has reported 135 cases of intestinal obstruction with a total mortality of 19.2 per cent. Of these 135 patients, 51 came directly to Holden. There were only three deaths in this group, a mortality of 6 per cent made possible by early recognition of the presence of obstruction and prompt surgical interference. The key to better results in the treatment of intestinal obstruction is early diagnosis.

PATHOLOGY

Classification:

From the point of view of a pathological division there are essentially two types of intestinal obstruction, viz., simple and strangulation obstruction. In the former group are included all cases in which a block in the continuity of the bowel exists; in the strangulation group are those which exhibit in addition to a mechanical block, evidence of deprivation of blood supply to the intestine.

The bowel wall above the obstructing mechanism is distended, hyperemic and thinned out in obstructions of an acute nature. Fluids and gas accumulate in the proximal segments in large amounts. Microscopically partial erosion of the intestinal villi or mucous membrane may be seen together with edema and hemorrhage throughout the layers of the bowel wall. The bowel distal to the obstruction is anatomically normal. The imprisoned loop in well-developed strangulation obstruction is infarcted, exhibiting discoloration and signs of tissue death. In simple obstruction to the continuity of the bowel, in which the dis-

CLASSIFICATION OF INTESTINAL OBSTRUCTION

A. *MECHANICAL*
  I. NARROWING OF LUMEN — SIMPLE
    1. Strictures of bowel wall
      a. Congenital { Atresia, Imperforate anus
      b. Acquired { Inflammatory, Traumatic, Vascular, Neoplastic
    2. Obturation
    3. Compression from without (Especially pelvis and retroperitoneal duodenum)
  II. ADHESIVE BANDS { Congenital, Inflammatory, Traumatic, Neoplastic } SIMPLE OR STRANGULATION
  III. HERNIA
    1. External—STRANGULATION (with only few exceptions)
    2. Internal—STRANGULATION (usually)
  IV. VOLVULUS—STRANGULATION
  V. INTUSSUSCEPTION—STRANGULATION
B. *NERVOUS*

  II. SPASTIC ILEUS (Dynamic)—SIMPLE
C. *VASCULAR*
  I. THROMBOSIS AND EMBOLISM OF MESENTERIC VESSELS
  II. SEVERANCE OR INJURY OF MESENTERIC VESSELS (Operative or blunt trauma) STRANGULATION

tension is great enough to impede the free arterial inflow of blood to the intestine and egress of the venous return, the phenomena of devitalization as observed in strangulation obstruction may ensue. This occurrence is not infrequently observed in the cecum consequent upon the enormous distension of the colon occasionally accompanying carcinomatous obstruction in the sigmoid flexure. As a consequence, distension ulcers, perforation, and gangrene may follow, as are regularly observed in non-viable strangulated segments.

From the point of view of causative factors, three main types of intestinal obstruction may be recognized, viz., mechanical, nervous, and vascular. This division furnishes an adequate and satisfactory clinical classification, into one of which categories any observed variety of intestinal obstruction may be easily placed. By far the larger number of instances of obstruction are due to mechanical agents such as adhesive bands, hernia, neoplasms, intussusception, and volvulus.

Cause of death:

The discovery of Hartwell and Hoguet, that dogs administered saline subcutaneously may survive complete obstruction of the upper intestine for as long as three weeks, has lent considerable impetus to the observational study of bowel obstruction. Since these observations were made our ideas concerning the mode of death in obstruction have undergone considerable change. In this brief paper devoted primarily to the elaboration of clinical criteria on which an early diagnosis can be made, the pathological physiology of bowel obstruction can be dealt with in only a summarical fashion.

There are many features of the problem that still remain unsolved. Whether the intestinal content above the obstruction is more toxic than normal intestinal content is a debatable issue. Some experiments performed by Chunn and me indicate that it is not. Whether abnormal absorption occurs from the lumen of a distended bowel to which the blood supply is not compromised is an even more important issue. A few older well known experimenters (Enderlen and Hotz, and Clairmont and Ranzi) have shown that the obstructed bowel is less permeable to substances ordinarily absorbed than is the normal intestine; and Loucks and I were unable to obtain evidence of the absorption of histamine in simple obstruction when histamine was placed proximal to the obstruction. Though such abnormal absorption may obtain, I do not know of a single bit of evidence which indicates that in simple obstruction in which the bowel wall is viable that it does occur. There is, however, considerable negative evidence in which no proof of abnormal absorption has been obtained.

In strangulation obstruction, on the contrary, autolysis of the mucosa of the devitalized bowel quickly occurs and abnormal absorption through the mesenteric blood vessels occurs as well as via the serous surfaces of the peritoneal cavity when the strangulated segment is no longer viable.[4]

In experimental obstruction of the upper intestine in the dog, the subcutaneous administration of saline serves as an antidote not for abnormal toxins absorbed, but as a substitute for vital fluids lost by vomiting. When saline is not given, death usually occurs within 3 or 4 days and a marked increase in the blood nonprotein nitrogen, a decrease in the blood chlorides, and an increased combining power of the blood for carbon dioxide obtains (alkalosis). The administration of saline precludes the occurrence of these alterations in the blood chemistry and prolongs the life of the animal. Even a temporary administration of saline for a few days will often permit the animal to live just as long as though it were given each day.[24] Animals with a complete duodenal fistula die in a few days and exhibit the same blood chemistry changes as do dogs with obstruction at the same level.[22] The administration of saline prolongs their lives and obviates the occurrence of the blood chemistry changes.

Dogs with complete obstruction in the lower colon usually survive for comparatively long periods. In our laboratory one dog has survived such an obstruction for 50 days. The usual cause of death is dehydration and starvation. The administration of saline does not prolong their lives and blood chemistry alterations are usually not observed.

Many phases of the cause of death in acute bowel obstruction are still imperfectly understood, but it would appear that there is a fairly direct correlation between the function of the part of the intestinal tract concerned and the cause of death.[26] Obstruction of the upper intestine produces changes in the blood chemistry and saline is an effective substitute. In low colon obstructions, alteration in the blood chemistry is unusual and saline exhibits no specific value as a remedial measure; similarly in experimental obstruction of the ileum. The dogs with low colon obstructions frequently survive for long periods whereas the dogs with ileal obstructions in which a good portion of the absorptive area is blocked out usually die within a week; saline does not prolong their lives. In strangulation obstructions, saline is of no special value as a therapeutic agent. These latter observations serve to emphasize the significance of the mechanical factors in bowel obstruction.

DIAGNOSIS OF INTESTINAL OBSTRUCTION

Symptoms:

Pain, vomiting, collapse, constipation, and meteorism have been the usual standards on which judgment has been based as to whether or not obstruction of the bowel exists. All of these phenomena may be observed at some time during the course of intestinal obstruction but their importance as measures of diagnostic value must be properly appraised. In his nonpareil text on the Principles and Practice of Medicine, the late Sir William Osler says, "The sequence of gastric, bilious, and finally stercoraceous vomiting is perhaps the most important diagnostic feature of acute obstruction." That this in part is true must be freely conceded, but it is decidedly unsafe to await confirmation of this succession of events. Similarly, absolute constipation, meteorism, and collapse may establish the diagnosis, but at a time when the patient is beyond hope and remedy.

Unlike other acute surgical lesions of the abdomen, simple obstruction of the intestine produces no local signs that help to corroborate the suspicion that obstruction may be present. Appendicitis, biliary colic, and perforation in the gastro-intestinal tract occasion definite physical findings that are of immense value in deciding the nature of the condition present. The recognition of the existence of acute inflammation of the vermiform appendix without the occurrence of local tenderness and rigidity would enhance the difficulties of diagnosis enormously; the number of cases coming to operation with peritonitis would be manifoldly increased should such difficulties exist.

Undoubtedly the absence of definite local physical findings more than any other factor accounts for the delay in the recognition of bowel obstruction. Were this point continuously borne in mind, the occurrence of crampy intermittent pain without abdominal tenderness would not be so lightly considered. At the same time, the absence of local symptoms should be of distinct value inasmuch as it obtains in no other serious surgical emergency that affects the abdominal viscera.

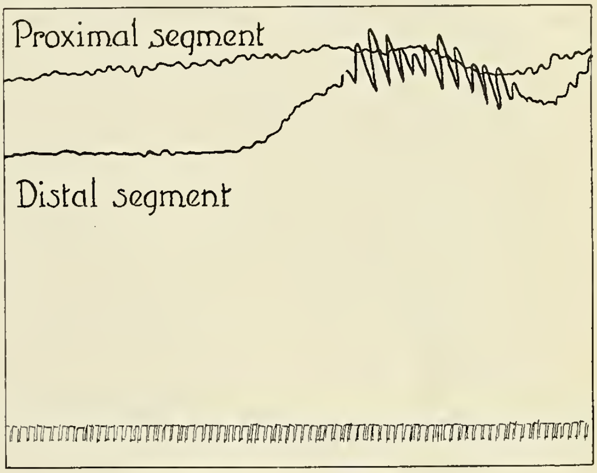

Fig. 1. Tracing made on a dog with complete intestinal obstruction of two days' duration. A balloon was inserted into the proximal segment and another into the segment distal to the obstruction. The peristaltic activity of this segment is apparent in the tracing.

Auscultation of the abdomen often lends the most valuable of all physical signs of obstruction. Visible peristalsis though regularly present in subacute and chronic obstructions is rarely observed in acute bowel obstruction. Loud peristaltic rushes like the bubbling sound produced by pouring water out of a bottle may be heard with the stethoscope when a mechanical obstruction exists. A dilated intestine in which considerable fluid and air are present is necessary to elicit these bubbling sounds. Near the point of intestinal occlusion these intestinal noises may attain an explosive force. Frequently a metallic tinkle may be heard, a sign of conclusive significance for the existence of a mechanical obstruction. As the fluid and air are carried downward toward the point of obstruction by peristaltic rushes, their progress is suddenly arrested and fluid and air which were intimately mixed in their advance tend to separate as the onward movement is halted. As the air rises to the surface, a sound like drops of water falling in a rain barrel may be heard. The metallic character of the sound has a high pitch imparted by the tension of the dilated intestine. Such sounds may also frequently be heard over the abdomen after an abdominal operation when the paresis of the intestine incident to the operation begins to be recovered from.

Mistrust in enemas:

A diagnostic criterion upon which too much emphasis has been placed in the recognition of acute bowel obstruction is the inability of the patient to expel gas or feces following the administration of an enema. There exists a general tendency to disbelieve the presence of a complete obstruction as long as gas or feces continue to be returned with the enema. Recently a patient came under my observation with enormous abdominal distension and regurgitant feculent vomiting. She had been operated upon a few weeks previously, and had persistent intermittent colicky pain and vomiting for four days before admission at the University Hospital; her physician, though suspecting bowel obstruction, had been unwilling to accept or commit himself to such a diagnosis because gas and feces continued to be expelled following the administration of enemas.

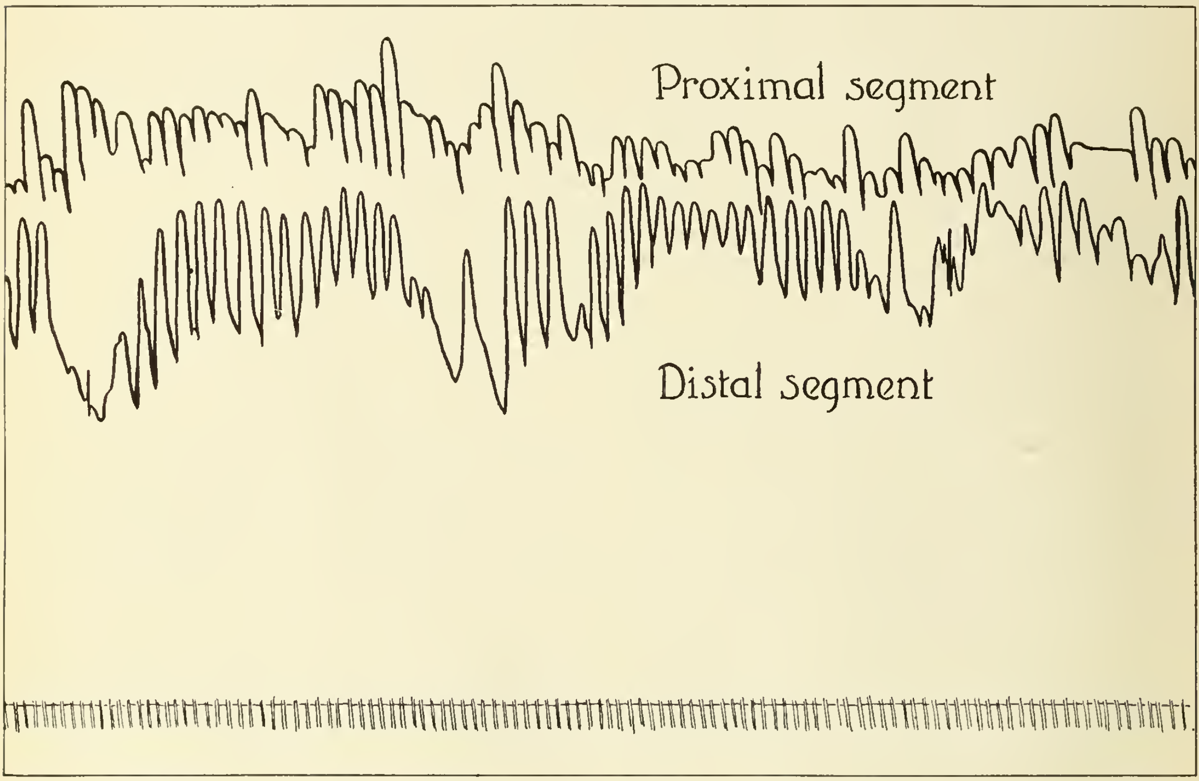

Fig. 2. A tracing made under conditions similar to those in Figure 1, with the exception that the record was obtained under spinal anesthesia. In this record the release from the inhibiting influence of the splanchnic nerves is apparent in the marked peristaltic activity of the intestinal contractions. The distal segment is fully as active as the proximal. The fallacy of considering the segment distal to the point of obstruction inactive is apparent from this tracing.

In the experimental laboratory it was found that, even after complete division and inversion of the ends of the intestine, enemas obtained gas as long as there was any present in the distal bowel.[25] By placing balloons in the bowel distal to the obstruction it was noted that the peristaltic activity compared favorably with that of the normal.[3] The bowel distal to the obstruction is physiologically as well as pathologically normal! Why shouldn't the bowel distal to the obstruction expel gas or feces following the administration of an enema? In high obstructions gas will continue to be expelled as long as rectal irrigations are given; in partial obstructions as long as some of the content of the bowel proximal to the obstruction finds its way into the distal segments gas will also continue to be expelled with enemas. Only in complete low obstructions are enemas of real value in the early recognition of acute bowel obstruction.

Value of x-ray in diagnosis:

It has long been recognized that the *x*-rays are of value in detecting bowel obstruction, but this agent has not been accorded the importance that it deserves in the diagnosis of acute intestinal obstruction.

When a single plate of the normal abdomen is made in the adult, gaseous shadows are usually observed in the stomach and colon. Gas is also present in the small intestine but the intimate admixture of gas and fluid in the small bowel precludes distinguishing the gas from its immediate surroundings. The demonstration of gas in the small intestine on the *x*-ray film is therefore decidedly abnormal and is indicative of the presence of a mechanism interfering with the normal rapid rate of transit through the small intestine. The ladder "patterns" described as the typical *x*-ray picture of bowel obstruction need not be awaited to make the diagnosis. Visible collections of gas in the small intestine of the adult are synonymous with intestinal stasis. In the experimental laboratory it has been found that definite *x*-ray evidence by the single plate method may be obtained within four or five hours after the obstruction.[28] When the plate is taken in the erect posture "fluid mirrors" can be made out in which air is layered over the fluid. These afford concrete proof of the presence of intestinal stasis. In patients too ill to stand, the same information may be obtained by taking the plate with the patient on his side.

It is to be remembered, however, that the mechanism for the production of such intestinal stasis may be either mechanical or inhibitive. The stethoscope will serve to differentiate! In the inhibition or paralytic ileus of peritonitis, auscultation reveals a relatively silent abdomen, occasionally as silent as the "stillness of the grave." In mechanical obstruction on the contrary, loud

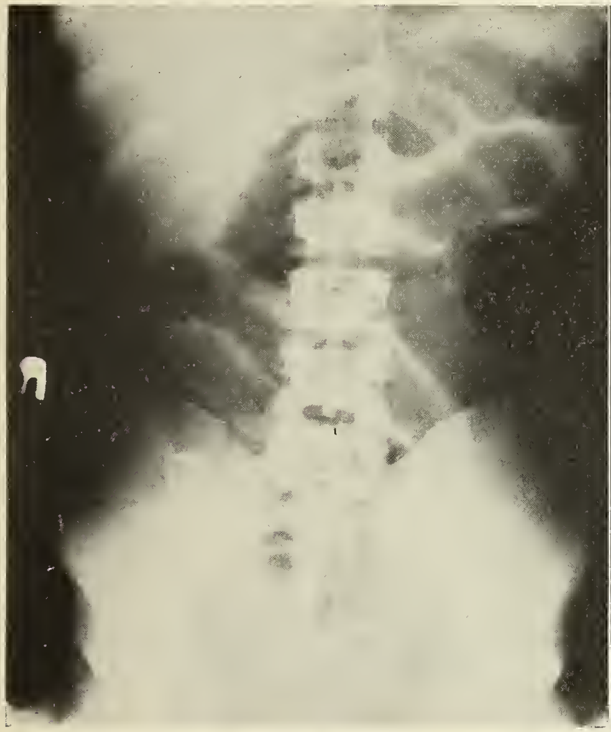

Fig. 3. A flat plate made of the abdomen in a case of peritonitis in which the entire intestinal tract is distended. In mechanical obstruction of the intestine the bowel above the point of obstruction alone is distended—another bit of evidence for the intestinal stasis being due to peristaltic ileus (inhibitive ileus) is that the intestinal wall between the dilated loops seems unusually thick in places; this appearance is afforded by the presence of exudate between the intestinal loops. This patient, of course, had abdominal tenderness and rigidity, which are almost invariably absent in simple intestinal obstruction. Auscultation of the abdomen failed to elicit loud peristaltic noises.

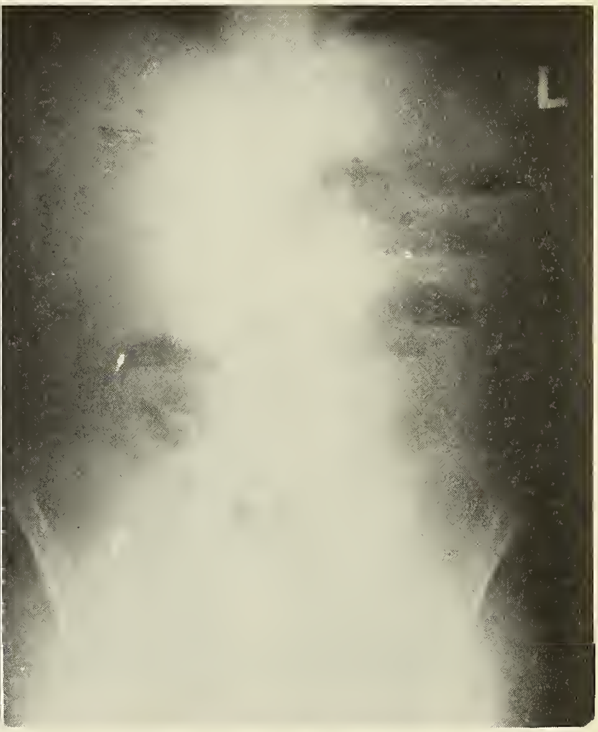

Fig. 4. Single plate of the abdomen made in the erect posture from the same patient as shown in Figure 3. The "fluid mirrors" in the small intestine indicative of intestinal stasis are well shown. The stethoscope in such cases serves as the best differential to determine whether the stasis is of mechanical or inhibitive origin.

borborygmi and frequently metallic tinkles are to be heard.

The oral administration of barium is of no value in the recognition of most cases of acute bowel obstruction and usually only contributes to unnecessary procrastination in arriving at the diagnosis.

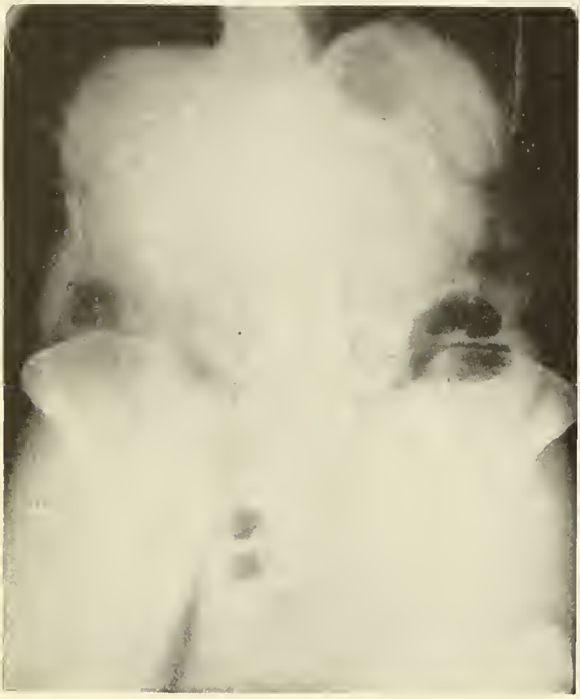

Fig. 5. A single plate taken of the abdomen of a patient who had complained of intermittent crampy pain of seven hour's duration. There had been considerable vomiting, but physical examination of the abdomen was negative. A previous enema had evacuated most of the gas in the colon; the loop on the left, however, indicates the abnormal presence of gas in the small intestine. Loud peristaltic borborygmi were heard on auscultation. The "ladder pattern" of intestinal obstruction as shown in Figure 3 is not necessary for the diagnosis of obstruction because the visualization of gas in the small intestine in the adult is significant of intestinal stasis.

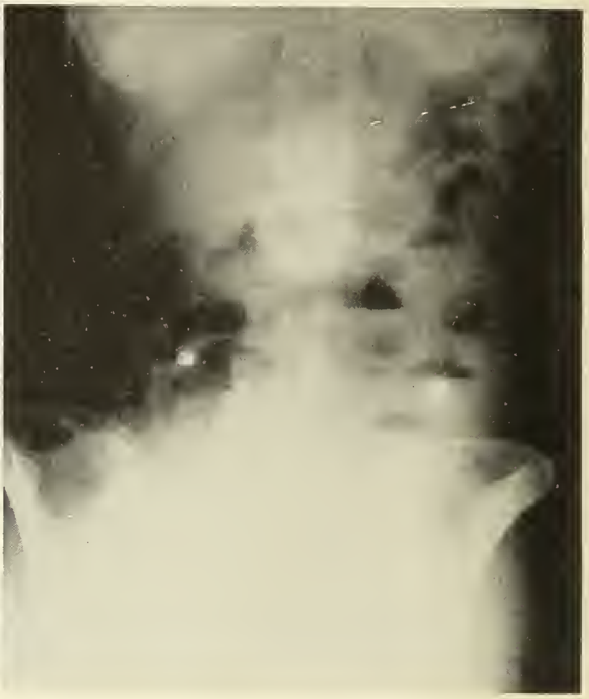

Fig. 6. Plate made of the abdomen in the erect posture in a patient with intermittent crampy pain of twelve hours' duration. The "fluid mirrors" indicate the presence of intestinal stasis. The stethoscope as well as the crampy pains serve to designate the mechanical origin of the obstruction.

General condition:

Early in the course of simple obstruction the general condition of the patient is good. The crampy intermittent pain and nausea and vomiting make him ill at ease, but he may not appear especially sick. The body temperature is normal and continues so until late in the disease, when subnormal or, less often, elevations of slight degree may be recorded. There is ordinarily but slight quickening of the pulse and no change in blood pressure until prolonged continuance of the obstruction ushers in circulatory collapse as manifested by hurried feeble pulse, cold and livid extremities, and pinched and sunken features, an anxious expression and great restlessness. Leukocytosis is absent early; later, incident to the dehydration brought about by vomiting, high leukocyte counts may be obtained with similar increases in the hemoglobin and red blood cells. Blood urea elevation, plasma chloride decrease and an alkalosis occur with regularity in high obstructions only and are not an early sign of acute bowel obstruction. Late in the disease, the tongue is parched and great thirst is complained of; the urine is scant and of high specific gravity and may contain albumin and indican. Alterations in respiration are dependent largely upon the presence or absence of distension. Late in the course of intestinal obstruction rapid superficial respirations are the rule. The sensorium remains clear until near the end when the sinister warnings of euphoria, delirium and coma portend the approach of impending death.

One of the greatest evils in the management of cases of intestinal obstruction has been the administration of morphine under the impression that no serious disorder exists. Both physician and patient are pleasantly lulled into a sense of temporary security by this disguise, and the significant warning of pain is silenced until physician and patient are rudely awakened, but often too late to undo the harm wrought by the irremediable delay. A patient presenting intermittent colicky abdominal distress without localizing findings should be watched carefully. Such a patient should be under careful hourly scrutiny and preferably in a hospital. If intermittent pain continues despite the return of gas following the administration of enemas, the abdomen should be opened. It is far better, as C. H. Mayo has so wisely said, to open an occasional abdomen unnecessarily than to await the textbook picture of intestinal obstruction. If the criteria of obstruction elaborated above are adjudged properly, such an occurrence will be most unusual.

SYMPTOMS OF STRANGULATION OBSTRUCTION

When in addition to a block in the continuity of the bowel, the intestine is deprived of its source of blood supply, a different clinical picture obtains than is observed in simple obstruction. Such a patient is more acutely ill; the pain is often agonizing in character; the pulse is usually quickened early in the course of the ailment and fever of 100°-101° is not unusual and higher temperatures may be recorded. The breathing is superficial and more frequent than normal. When a large segment of intestine is involved in the strangulating mechanism, symptoms of collapse may occur. Urinary suppression during the continuance of the strangulation is usual.

The clinical picture is determined by the degree of arrest of blood flow to and from the strangulated segment. When this is marked, symptoms of strangulation predominate; when the deprivation of blood flow is less prominent, the symptoms of mechanical obstruction dominate the picture. Every gradation from mimicry of the picture of simple obstruction to profound shock may be manifested.

In strangulation obstruction local physical findings in the abdomen are almost invariably present. Most strangulation obstructions present the features of a closed loop obstruction in which the distension of the obstructed segments progresses at a rapid rate. Consequent upon the infarction of the intestine, peritoneal irritation may usually be elicited by the demonstration of rebound tenderness. The accumulation of gas in the intestine and infarction of its wall may render the involved segment easily demonstrable by percussion and palpation of the abdomen. Wahl described this phenomenon a number of years ago and the presence of such a tympanitic mass is usually known as Wahl's sign. Such a loop may occasionally be noted on careful inspection of the abdomen. When a short segment of small intestine is concerned in the strangulation this sign may be absent due to the concealment of the involved intestine by other coils of bowel. Tenderness is usually present over the mass and the latter imparts to the palpating hand an elastic resistance. The coil is usually fixed and exhibits no peristalsis. The intestine above the obstruction distends gradually but it has been found in the experimental laboratory that the gaseous shadows in the small intestine do not appear as early in strangulation obstruction as in simple obstruction and that the X-ray is therefore not as valuable in the early diagnosis.[10a] Loud, peristaltic rushes may be heard from the contractions of the intestine proximal to the obstruction. The bowel below the obstruction being normal may evacuate feces and gas on the administration of an enema. Later in the course of the ailment an inhibition ileus as may be seen in kidney colic or peritonitis may supervene and the abdomen becomes relatively silent and enemas are not expelled.

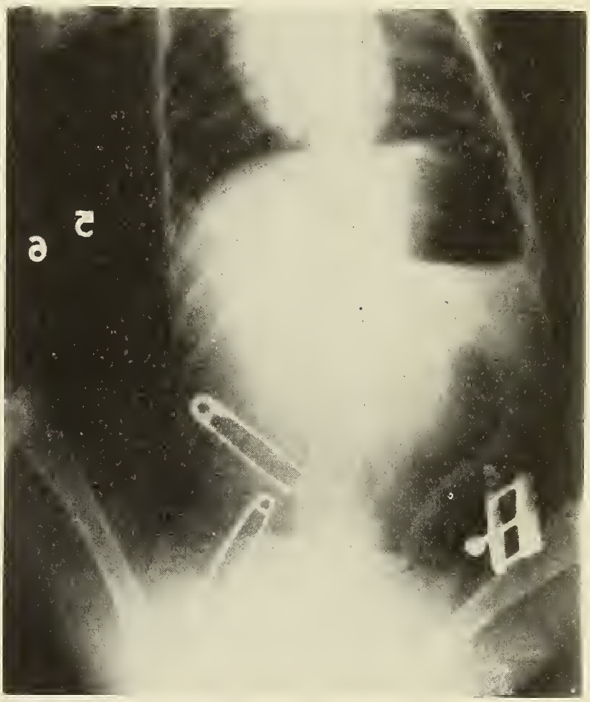

Fig. 7. Intestinal obstruction in a dog four hours after the establishment of complete obstruction in the lower ileum. Experimental study with *x*-ray of gaseous shadows in the intestine after obstruction indicates that reliable evidence can be obtained by this method within four to five hours after obstruction.

Vomiting of a reflex nature sets in early after the onset of pain but ordinarily does not continue in the same degree as seen in simple obstruction. Blood in the stool is not infrequent and its occurrence in the vomitus in high strangulations has been observed. If the course of the disease continued uninterrupted, the beginning of the end of life is heralded for the sufferer by extreme restlessness, a feeble thready pulse, a cyanotic appearance of the skin which is cold and moist with sweat, and general signs of circulatory failure. If the strangulated bowel becomes non-viable, peritonitis supervenes and hiccough frequently manifests this occurrence. It is to be remembered, however, that, although the course of strangulation obstruction is ordinarily unusually rapid owing to the deprivation of blood supply of a portion of the intestine, such is not an invariable occurrence. When the strangulating features are less prominent, the progress of the disease simulates the picture seen in mechanical obstruction at the same level, and it has not been an extremely rare observation to find a short infarcted loop as a consequence of thrombosis of the vessels in a segment of the mesentery go entirely unsuspected for more than a week's time, manifesting some abdominal discomfort, but not sufficient to warn the surgeon or patient of the lurking danger.

TREATMENT

When to operate:

The essence of the treatment of acute bowel obstruction is early diagnosis and early surgical intervention. Operation must not be deferred until the nature and location of the obstruction are known. This information can be more accurately determined at operation with less risk to the patient than if surgical interference is put off until all these queries can be satisfactorily answered. When it is appreciated that it is most important to recognize bowel obstruction early a large number of operations will be in the nature of an exploratory procedure as to the type of lesion that will have to be dealt with. Unfortunately, at the present time a large proportion of the operations performed for the relief of bowel obstruction are in the nature of resuscitations, and failures and bitter disappointments are numerous.

Preoperative preparation:

When the decision to operate has been made, no great time should be lost in preoperative preparation. During the hour that preparations are being made in the operating room, the patient's stomach should be evacuated with a tube and a liter or two of normal saline given intravenously and subcutaneously. There is an impression not infrequently encountered amongst physicians that it is more important to put off operation for eight to ten hours, during which time the patient's condition is being "built-up" with free administration of glucose and saline. Though salt and water are important agents in combating the dehydration of obstruction, it must be remembered as has already been pointed out above that only in high obstructions do these therapeutic agents exhibit the virtues of a specific.

How to operate:

When patients come to operation early the choice of an anesthetic is not so important. But to administer inhalation anesthesia to a patient with regurgitant vomiting and considerable distension, even though the stomach is emptied by a tube immediately before the administration of the anesthetic, is a hazardous undertaking.

Spinal anesthesia is the ideal analgesic agent for cases of intestinal obstruction. At the University Hospital we have employed it with complete satisfaction to the exclusion of all other types of anesthetics in intestinal obstruction except in infants, in whom local infiltration of the abdominal wall with procaine combined occasionally with light ether anesthesia usually suffices. It is somewhat outside the province of this paper to discuss the stimulating effect of spinal anesthesia on the distended bowel in paralytic ileus. No harm is to be anticipated, however, in administering spinal anesthesia because of the induced increased intestinal activity in the presence of a mechanical obstruction when immediate operation is to be performed. The early history of the employment of spinal anesthesia is a dark chapter, but recognition of the fact that the Trendelenburg position and not the upright posture protects the patient, and the introduction of ephedrin to support the blood pressure have made its use safe. Within the past year I have been enabled with its employment to operate successfully upon several late cases that would not have tolerated operation under inhalation anesthesia. Only in moribund patients is its use contraindicated.

The incision:

Unless it is definitely known just where the obstruction is, it is best to make a mid-line subumbilical incision, or a midright rectus opening of the peritoneal cavity. Most instances of small bowel obstruction can be approached satisfactorily through such an opening. In the presence of a large bowel malignancy in which a colostomy is found to be the procedure of choice, a short oblique inguinal incision can be made in either groin and the establishment of the colon decompression facilitated through the midline incision.

Location of obstruction:

In locating the point of obstruction, it is always wisest to hold up the abdominal wall first with retractors and look inside. The employment of spinal anesthesia permits easy and wide retraction of the abdominal walls and frequently exposes the site of obstruction, especially if the intestine is adherent to the parietal peritoneum. In disregarding this simplest of procedures the obstruction may not be located after diligent search with the hand in the abdomen. Short of a routine "going over" of the entire intestine, it is the most efficient method by which to locate the obstruction.

Many years ago Greig-Smith pointed out that a distended coil in the proximity of the site of occlusion will usually present itself into the wound. If the point of obstruction does not immediately come into direct vision, pursuit of the coil in the direction that presents itself least readily will usually lead to the obstruction. In addition, the intestine immediately above the point of obstruction will be hyperemic as well as dilated. When cases of intestinal obstruction are operated upon earlier, exploratory examination can be more deliberate and these signs are not as important. At least some of these cases, however, will always be with us and we must be prepared to treat them most efficiently.

Choice of procedure:

The most important decision the surgeon has to make when operating for intestinal obstruction is whether it will be possible to do the operation of election, viz., to find and relieve the obstruction and restore the continuity of the bowel or whether he must content himself with a simple drainage operation. The nature of the obstruction will in part decide this matter. In a strangulation type of obstruction in which a segment is deprived of its blood supply it is apparent that a choice of the magnitude of operation that the patient can best tolerate must not determine the procedure to be followed. Relief of the mechanical block in the bowel by enterostomy or release of the strangulating mechanism alone will not suffice; excision or exteriorization of the devitalized bowel must also be done. The continuance of such a segment in the abdomen is not compatible with recovery. The performance of a simple drainage operation in the presence of strangulation obstruction advanced to the degree of loss of vitality is therefore futile.

Immediate determination as to type of obstruction present must, therefore, be decided. The occurrence of bloody fluid in the peritoneal cavity signals the presence of a strangulation obstruction. In carcinosis of the peritoneum or in a low grade peritonitis, fluid may be present, but it is usually serous in character. An infarcted coil of intestine lends confirmation of the presence of a strangulation obstruction.

The course of action must depend solely on whether or not the bowel is viable. The return of normal color to the bowel and the return of pulsation in the vessels of the mesentery after reduction of the strangulation herald the viability of the bowel. In doubtful cases the decision as to what is best to do may be a difficult one. When the condition of the patient permits, a resection with end-to-end or lateral anastomosis is the most conservative procedure; damaged bowel proximal to the strangulation must be excised generously. It is a hazardous procedure to perform an anastomosis on a distended hemorrhagic bowel. In ill patients it is much the wiser plan to exteriorize the gangrenous bowel even in the small intestine and perform a secondary anastomosis later. If the fistula following exteriorization proves to be high in the small intestine the content from the upper loop should be collected with a catheter and put into the distal segment. The bowel wall of the strangulated segment may be edematous, but there should be no sharp line of demarcation of color between the normal and the involved intestine. When edema persists, the normal luster and sheen of the peritoneal surface of the bowel may not return promptly. Normal contractile response to pinching is absent in the nonviable bowel.

When a strangulation obstruction is not present, the surgeon in his selection of operative procedure should permit himself to be guided entirely by the patient's condition. In the early case, the operation of election may be performed, viz., the determination of the location of the obstruction and its release. In the precarious risk, the absence of a strangulation obstruction is indication for the performance of decompression by enterostomy. The determination of the location and exact nature of the obstruction in such cases is made at the risk of inviting disaster. Suppression of curiosity on the part of the surgeon at such a time will afford him an opportunity to determine later in a living patient what need be done. It should be remembered that, though the persistent existence of adhesive bands in the small intestine are potential forerunners of subsequent intestinal obstruction, such a patient may find himself so free from symptoms as to be unwilling later to submit to more surgery.

In early cases of simple obstruction, location of the point of obstruction and evisceration of the intestine in its search may be practised with safety and equanimity. Evacuation of the intestinal content by enterostomy in such cases may be dispensed with as unnecessary. All anastomotic procedures on the dilated intestine are to be religiously avoided. Tissues partially devascularized by long continued compression of the blood vessels of the bowel wall consequent upon the intestinal distension do not permit safe suture.

In postoperative obstructions, enterostomy as a single therapeutic agent serves its widest field of usefulness. Consequent upon the subsidence of intestinal distension brought about by enterostomy, the continuity of the intestine is frequently automatically reestablished and the enterostomy opening closes spontaneously when the safety vent has served its purpose upon withdrawal of the tube.

The statistical mortality in this group of cases is surprisingly high. The late recognition of the cases is in large part responsible for this high death rate, but the tendency to performance of operations of election rather than the adaptation of a procedure suitable to the precarious condition of the patient contributes in no small degree to the persistence of a forbidding mortality in this group. Evisceration of the intestine to locate the site of obstruction, or the manual manipulation and examination of long segments within the abdomen, and prolonged operative procedure incident to their performance robs the ill patient with late simple obstruction of a large margin of his chance for recovery.

Selection of site for enterostomy:

A distended coil of intestine above but near the point of obstruction should be chosen as the site of enterostomy. The deliberate performance of a jejunostomy in each case is not only unnecessary but harmful. The exponents (Bonney) of high drainage of the intestine in obstruction have insisted that the tapping of the fluid and gas containing segment is all-important. In addition, it was erroneously contended that such a vent permits escape of the most toxic intestinal content. The danger of a high intestinal fistula, per se, has been adequately demonstrated. Haden and Orr have been able to show that in the dog even partial escape of the jejunal content through catheter drainage always proves fatal. High jejunostomy therefore unless inevitable because of the location of the obstruction is to be deliberately avoided.

Technic of enterostomy:

In the performance of enterostomy fine needles and suture material, preferably silk, are to be employed. When conditions permit, it is a good plan to draw out the loop upon which enterostomy is to be done and isolate it in one or between two rubber covered clamps. Puncture of the bowel wall with a fine needle followed by withdrawal of the content of the loop with an aspirating syringe will obviate the occurrence of leakage from the stitch holes. A urethral catheter (No. 16 French) is then buried in the bowel wall by the Witzel technic. When possible the catheter should be drawn through the omentum and the latter should be fixed to the anterior abdominal wall. By placing the catheter on the stretch and making a superficial circular cut around it, about 4 or 5 inches from the eye, a groove is secured in which a fixation suture may be placed. When the traction on the catheter is released, the groove and knot in the suture are scarcely apparent. A fine chromic catgut suture is best employed to secure the catheter to the bowel wall. This refinement obviates the catheter's coming away before it has wholly fulfilled its intended purpose.

I do not believe that the employment of the Moynihan evacuation tube has any advantage; it exposes the intestine to unnecessary trauma and precious moments are wasted. When the distension is extreme, immediate evacuation of the bowel on the operating table by a trocar before suturing the catheter in place is commendable.

Postoperative treatment:

After operation the patient should be placed in bed so that respiration is unhampered. Semi-Fowler's position usually gives most comfort Physiologic sodium chloride solution is to be given daily subcutaneously with daily intravenous glucose (10 per cent) administration until the patient takes fluid well by mouth. The intake and output are to be carefully recorded; the vomitus or gastric retention recovered by expression are to be subtracted from the fluid intake. An optimum intake for a patient with intestinal obstruction in whom a considerable amount of fluid is being continuously dumped into the intestine, is in excess of the requirements of the ordinary abdominal surgical patient. In intestinal obstruction, only when salt begins to be excreted by the kidney does a diuresis occur. Three to four thousand cubic centimeters of fluid may well be utilized for the first few days. When the urine output approximates the normal, the intake may be decreased.

The patient with an enterostomy high in the intestine must be carefully watched for evidence of ill consequences from the loss of the high intestinal juices. When the effects of the obstruction have been successfully combated, the catheter may be intermittently clamped to determine the patency of the intestinal channel below. In the event that the enterostomy presents the only avenue of escape for the intestinal secretions, another catheter must be placed in the distal bowel into which the fluid collected from the oral loop may be placed, or a more direct attack on the obstructing mechanism must be made. The optimum time for such a procedure is when the patient exhibits the greatest improvement from the intestinal decompression.

SUMMARY AND CONCLUSIONS

The establishment of true criteria of bowel obstruction early in its course will help more than any single factor in bringing patients to operation at an advantageous hour and to a definite lowering of the present appalling mortality of the disease. Our textbook descriptions of intestinal obstruction should be labelled Antemortem Signs of the Disease. They do not indicate interference with the continuity of the intestinal lumen but herald impending dissolution. Regurgitant vomiting and distension must cease to be criteria awaited before a diagnosis can be made. Collapse in simple bowel obstruction should be relegated to the delineation of that antemortem status in which all vital functions rapidly depreciate and from which escape or resuscitation is unlikely.

Intermittent crampy pain, accompanied by nausea and considerable vomiting without abdominal rigidity or tenderness, is strongly suggestive of an acute block in the continuity of the intestine. The detection of loud intestinal noises on auscultation of the abdomen and the *x*-ray visualization of gas in the small intestine lend sufficient proof to make the diagnosis. The continuance of colicky pain despite the return of gas and feces on the administration of enemas constitutes sufficient indication for immediate operative intervention.

The management of cases of bowel obstruction in accordance with the principles outlined here will lead to the striking improvement in surgical results long since obtained in the surgery of other acute abdominal disasters.

HALEY'S M-O MAGNESIA-OIL NOT ACCEPTABLE FOR N. N. R. AND MAGNESIA-MINERAL OIL (25) HALEY OMITTED FROM N. R. R.

The Council on Pharmacy and Chemistry reports that Haley's M-O Magnesia-Oil (exploited with the emphasis on "Haley's M-O") is the name under which the Haley M-O Co., Inc., has marketed a mixture of magnesia magma (milk of magnesia) and liquid petrolatum; that the firm requested acceptance of the product for New and Non-official Remedies stating that it is composed of magma magnesiæ 75 per cent by volume and liquid petrolatum 25 per cent by volume, that the Council refused admission of the product to New and Non-official Remedies because the use of a mixture of liquid petrolatum and magnesia magma in fixed proportions under an uninforming name is detrimental to rational prescribing; and that the preparation was accepted after the firm had adopted the name Magnesia-Mineral Oil (25) Haley and had revised its advertising to make it acceptable. After the Council had repeatedly been obliged to object to the advertising, the firm wrote to the Council that its attempts to meet the requirements of the Council were proving financially unprofitable and that it had decided to go back to the old name, "Haley's M-O" This means that physicians will again be asked to use this simple pharmaceutical mixture under an uninforming name. The Council directed the omission of Magnesia-Mineral Oil (25) Haley from New and Non-official Remedies and declared Haley's M-O Magnesia-Oil ("Haley's M-O") unacceptable for New and Non-official Remedies. (Jour. A. M. A., April 5, 1930, p. 1067.)

FRACTURES OF THE PELVIS*

Owen W. Parker, M.D.
Ely, Minnesota

THE occurrence of fracture of the bones in man goes back to the dawn of history; Cotton says—in speaking of ankle joint fractures—since the Nordic first wore brogans. The study of Egyptologists proves that many thousands of years ago bones were broken and tied up with splints much as is done today.

We are living in the so-called "machine age," and while the industries have surrounded the machine with every possible safety device and have trained their employees to follow the slogan "safety first," still, because of the great expansion in industrialism, trauma still causes many injuries and the surgery of trauma is receiving more attention than ever before in the history of medicine. Interest in traumatic surgery and fractures particularly has been stimulated by the compensation laws, by the greater demand that has been made on the surgeon for good results, by compensation boards, by insurance companies, by employers, by the injured themselves, by the urge of our economic system to cut down costs and return the injured to work as soon as possible and by the increasing knowledge that has come from the use of the *x*-ray.

In reviewing the last 683 consecutive fractures occurring from 1922 to 1930 in our work at the Shipman Hospital, in which the service is principally with the iron mining industry, we have had nineteen pelvic fractures. From these figures it was found that pelvic fractures have occurred in about 3 per cent of all fractures. This is about the percentage reported at the present time by others. The consensus of opinion now seems to be that fractures of the pelvis are occurring much more frequently in proportion to the total number of fractures than they did thirty years ago and we find this true in our work. In a series of 324 fractures occurring in our work before 1910 only two pelvic fractures are recorded, whereas in this present series of only a little over two times as many fractures we have had nine times as many pelvic fractures. Sir William Wheeler of Dublin states that the figures of the older authorities as Von Bergmann, Mikulicz and others indicate that fractures of the pelvis constitute only 0.3 per cent of the total number of fractures. He feels that this is much lower than our present rate.

The cause of the decided increase in the number of pelvic fractures as compared to former times, and also in proportion to the total number of other fractures, is doubtless our "machine age" mentioned above; that is, the great development of machinery in industrialism, the great expansion of industry and also the great development in rapid transportation and in this connection especially the general use of the automobile by the public. The aeroplane can be included in this rapid transportation group. Since the advent of the automobile, more women and children have suffered pelvic fractures in proportion to the total number of persons than formerly. This of course is due to the fact that formerly nearly all pelvic fractures occurred in industry and therefore mostly amongst men. Now many women and children as well as men ride in automobiles and also ride in other vehicles of rapid transportation and receive pelvic fractures in accidents of transportation and also on the streets, as pedestrians, by being struck by these rapid transports. We must not forget, however, that the industrial organizations are doing everything in their power to cut down the total number of injuries by placing all safeguards possible around all machinery to prevent men from being injured and also by training the man himself in safety-first methods so that he will be careful of his own safety; and transportation companies are doing likewise. But, we can not say as much for the people themselves who in driving their own automobiles do not show, in the mass, the same degree of care for prevention of accidents that the industries do. Automobile accidents are increasing, and whereas in former times pelvic fractures were cared for in hospitals connected with industry, now, with the automobile in such general use, any physician anywhere may be called upon to treat a severe pelvic fracture any time.

---

*Presented at the annual meeting of the Minnesota State Medical Association, Duluth, July 15, 1930.

It is interesting to note that just as the seriousness of a head injury depends not on the bony injury or fracturing of the skull but on the injury of the contents of the skull, namely, the brain and its coverings, so the bony injury or fracturing of the pelvis is not nearly so serious a matter as the injury that may have occurred to the soft structures within and about the pelvis. Thus a torn urethra, a ruptured bladder, a ruptured kidney, a perforated intestine, a ruptured blood vessel of which the iliacs, the obturators, gluteals, and pudic are most likely to be injured, is far more serious than multiple fractures of the pelvis and separation of the symphysis pubis or sacro-iliac joints.

It is rather remarkable the large amount of fracturing and displacement of fragments that may occur in the pelvis in which an excellent functional result is obtained in spite of a poor anatomical result. Perhaps this is more true of the pelvis than of the fracture of any other bones. Nevertheless, we should strive to obtain as good anatomical reposition as possible, just as we do in all other fractures. Striving to get perfect anatomical reposition has become almost our greatest thought in treating fractures since the use of the *x*-ray. Patients and their friends seem to expect perfect end-to-end "cabinet joiners" apposition when shown an *x*-ray plate of a fracture reduction; and likewise courts and juries. This consequently has a tendency to force more attention to perfect anatomical reposition than to perfect function—perfect function, however, being the far more important consideration. Nevertheless, we may say in general in the handling of fractures, the better the anatomial result, the better the functional result. Yet good functional result may be obtained without end-to-end apposition, especially in shaft fractures, if good alignment is maintained. In fractures near joints and into joints we like to get as perfect apposition as possible.

In this series of nineteen pelvic fractures, there were two deaths (a little over 10 per cent). Other reports show a similar mortality rate. Noland and Conwell in reporting 125 pelvic fractures had twenty deaths (16 per cent). The mortality rate shows the seriousness of many of these pelvic fractures. There were seventeen males and two females. All were adults, ages ranging from nineteen to sixty-six or an average of 37.5 years. The total number of hospital days was 736 or an average of almost thirty-nine days in the hospital in the whole nineteen cases. Counting the twelve persons who actually stayed in the hospital for the full time of hospital treatment the average time was fifty-seven days, the longest 128 days and the shortest twenty-two days. Noland and Conwell in their series of 125 cases report an average of sixty-five days in the hospital, the longest period being 133 days. The average time before resuming work of twelve patients traced was 194 days. The longest time off was 437 days. The shortest was ninety-three days. In Noland and Conwell's 125 cases, the average number of days lost was 175. The total number of pelvic fractures was forty. The total number of other fractures accompanying the pelvic injury was sixteen. The sum total of all fractures was fifty-six. The largest number of pelvic fractures in one person was seven. The largest number of other fractures in one person was seven. The largest number of all fractures in one person was nine.

Classified anatomically there were the following fractures:

Ilium	10
Pubis	
Horizontal or superior ramus	10
Descending ramus	8
Body	2
Total pubic bone fractures	20
Ischium	
Ascending ramus	2
Sacrum	1
Acetabulum	1
Symphysis pubis separation	2
Sacro-iliac separation	4

The complications occurring were: ruptured kidney, injured ureter, ruptured bladder, traumatic asphyxia, fractured ribs, fractured transverse processes, spinus processes and lamina of the lumbar spine, fractured scapula, double fracture of the clavicle, spinal cord injury with paralysis, foot drop due to peroneal nerve injury, hematomas at various regions of the pelvis and back, contused ankle, scalp wound, concussion of the brain, and blood in the urine. G. G. Davis regards peroneal nerve injury as occurring originally in the lumbo-sacral cord at the pelvic brim.

The causes of injury were as follows: eight occurred in the iron mining industry due mostly to being squeezed or rolled between a car and a timber; four were from automobile accidents, three while riding in cars and one by being struck by a car; two from gunshot wounds, accidental; one by being struck by a large piece of steel in construction work; one falling from a height of thirty-five feet; one by being knocked down by a cow and jumped on; and two in the lumbering industry, one from a falling tree and one from falling down a skidway and being struck by rolling logs. Eleven were industrial and eight civilian accidents. Blood in the urine occurred five times. Noland and Conwell reporting 125 pelvic fractures noted blood in the urine in sixty cases.

Many of these patients with pelvic fractures are in a severe state of shock on admission and first need to receive treatment for this condition. Their greatest complaint is of pain. It has been stated that some of them fear they will "fall to pieces." In the severe cases the abdomen seems continuous with the thighs. The Poupart ligament demarkations appear obliterated. There will often be other injuries besides the pelvic fracture, as the injuries are usually produced by great violence, although some are produced by slight trauma and have no complications or shock and no displacement of fragments and are consequently very simple to treat. An *x*-ray should be taken as soon as possible, and since the advent of the Bucky diaphragm this has become comparatively easy. It will immediately show the bony injury and obviate the necessity of too severe a physical examination in a very seriously injured patient. It will not, however, tell us the amount of injury to the soft parts, which, after all, is the most important thing to know. A specimen of urine should be obtained at once, by catheterization if necessary. If gross blood is found, an immediate attempt should be made to find its source. It may of course come from any point of the genito-urinary tract. Blood, however, may occur in the urine without any rupture of a viscus, probably due to a traumatization of the mucous membrane along the tract. Presence of blood indicates injury but gives little help in determining the source. If the urethra is ruptured, the catheter usually meets obstruction near its membranous portion. A perineal urethrotomy should be done if the urethra is seriously injured. If the ends of the urethra can not be found or united, the bladder should be opened suprapubically and a retrograde catherization done, another catheter being passed from the distal end of the urethra. The ends of the two catheters are threaded together, and traction on one directs the other through the two portions of the urethra. The ends of the urethra can thus usually be sutured over the remaining indwelling catheter. If the ends can not be brought together, they are simply held with tension-sutures. The catheter is left in place and the urethra will usually fill in the gap. This is a similar method to the one McArthur uses in repairing a cut common duct. It is surprising how well the urethra will take care of itself if given a chance. For a number of months after healing is secured, it will be necessary to pass sounds to prevent strictures. We have used this method in repairing injured urethras although we have had no injured urethras in our pelvic fractures.

Peacock in an analysis of twenty-eight cases of ruptured urethras found 71 per cent associated with fractured pelvis. On the other hand, he found only 9.8 per cent of fractured pelves that presented rupture of the urethra.

It is not always easy to decide whether a patient has a ruptured bladder and often requires fine judgment in making a diagnosis. The diagnosis may often be made only at operation, since the evidence will usually point to the probable rupture or perforation of some viscus in the abdomen and the condition of the patient usually does not warrant prolonged study. On opening the peritoneum, blood and urine are found and a tear in the bladder exposed.

Livingston, in the American Journal of Surgery, states that bladder rupture is by no means frequent (being encountered in one in 3,000 general surgical cases) but the high mortality of this accident justifies its careful study (30 to 80 per cent mortality even under the most favorable conditions). Bladder rupture is always due to trauma but the accident is favored by vesical distention, alcoholism and pre-existing diseases of the vesical walls. It is often observed with fractures of the pelvis. Twenty-five per cent of the patients with pelvic fractures suffer simultaneous bladder injuries. Ninety per cent of cases of bladder rupture occur in males due to the more violent nature of their activities, also to the greater depth of the female pelvis and the interposition of the uterus between the bladder and the vertebral column.

Quain, in 1916, reviewed the literature and reported 126 cases of rupture of the bladder all associated with fracture of the pelvis. The first case reported occurred in 1795. The patient, a man, was crushed under a wall and as a result there was a rupture of the bladder and the symphysis pubis was separated. The patient died 56 hours later. Autopsy showed infiltration of urine and peritonitis.

When bladder injury is suspected and the patient has a strong desire to urinate but is unable to do so, immediate catheterization should be done. If no urine returns, it may be due to an anuria from shock or to an intraperitoneal rupture with escape of urine into the peritoneal cavity. Usually the catheter passes freely through the urethra but only a small amount of urine is obtained with some blood, or more bloody urine may be drained away than could have been contained in the bladder, the urine having poured back into the torn bladder from the peritoneal cavity. In making a diagnosis some authorities suggest that a measured quantity of fluid should be injected and the fluid returned carefully noted and checked. There are disadvantages to this procedure. If the injected fluid leaks through a rupture into the peritoneal cavity, the desired information is obtained but the shock from which the patient suffers becomes more pronounced. If it returns in full quantity, it may have passed through an extraperitoneal rupture into the space of Retzius and returned with no appreciable diminution of quantity. Under such circumstances, the surgeon is deceived. In bladder ruptures either extra- or intraperitoneal, if the rupture is very small, a considerable quantity of urine, probably blood stained, will be recovered by catheter, as very little may leak out and no information as to the presence or absence of the rupture will be definite. Cystoscopic examination will assist in these cases. Injection of 150 to 200 c.c. of air into the bladder, followed by an *x*-ray, has been advocated. If air has passed into the peritoneal cavity it will form a bubble in the subphrenic area and if not visualized an intact bladder is presumed.

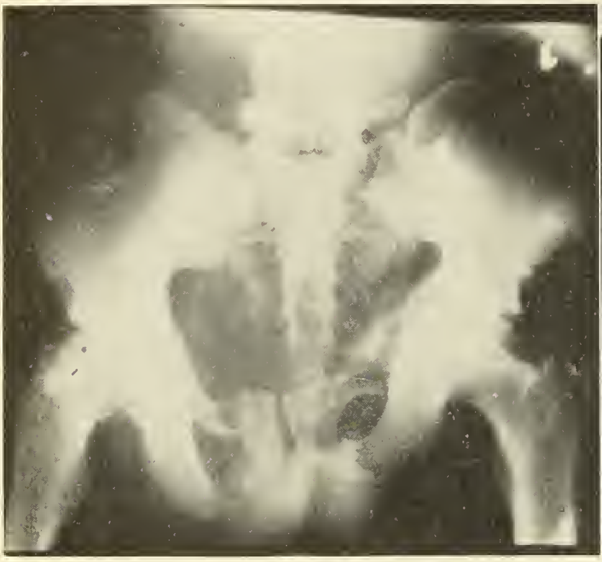

Fig. 1. Case 4.—J. V. Fracture of the left ala of the ilium; fracture of the horizontal ramus of the left pubis; fracture of the horizontal ramus of the right pubis; fracture of the descending ramus of the right pubis; fracture of the transverse processes of the two lower lumbar vertebræ. Ruptured bladder—death.

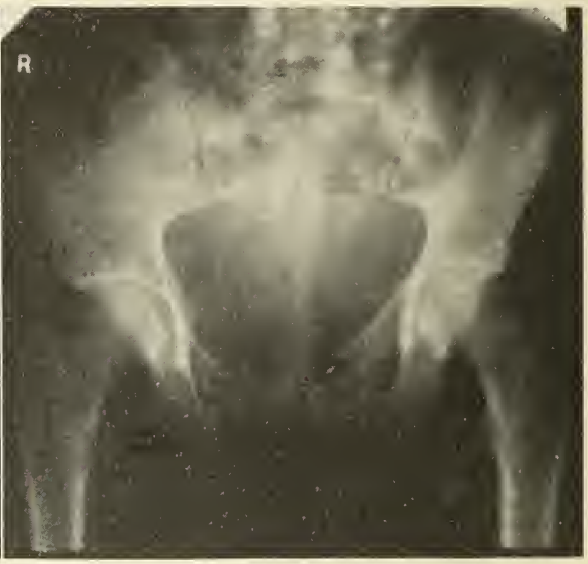

Fig. 2. Case 6.—E. M. Fracture of the horizontal ramus of the right pubic bone; fracture of the descending ramus of the right pubic bone; fracture of the horizontal ramus of the left pubic bone; fracture of the descending ramus of the left pubic bone. Later complicated by an attack of acute appendicitis—operation—recovery.

Rupture of the bladder is often produced by a spicule of bone, perhaps more often than by the bursting effect of the trauma. This was true in Quain's report of 126 cases. The rupture is either intra- or extraperitoneal. If intraperitoneal, which is more common, it is usually near the fundus or posteriorly. The urine escapes either into the space of Retzius and percolates toward the anterior wall or, as is more often the case, it escapes into the peritoneal cavity. In operation, the abdominal cavity is opened, all urine and blood removed from the cavity, the bladder sutured tightly with catgut (silk has also been used), and a self-retaining catheter is left in the bladder. Sometimes it is necessary to drain the abdominal wall down to the suture line of the bladder. Suture of the bladder has been considered unnecessary by some authorities if the bladder is thoroughly drained. We would ordinarily prefer suture. If the tear is extraperitoneal, it is usually on the anterior surface, either in an accessible portion or down below in the neighborhood of the trigone and post-prostatic area, and if not drained by immediate operation urine will eventually come to the surface through the inguinal canal, the femoral opening into the perineum or prevesical space. In our series there was only one case of proven rupture of the bladder.

In only one of our cases did there appear to be injury to the kidney. We thought the patient probably had a rupture of the kidney. This diagnosis was based on exclusion of the urethra and bladder, the presence of nearly pure blood in the urine, the large mass that formed in the region of the kidney which seemed to be due to hemorrhage, the history of the injury (the patient being struck in the region of the kidney by a heavy piece of steel), and the *x*-ray findings of fracture of the twelfth rib and of the ilium on the same side. We did not operate because, after treatment of the shock, the patient within a few hours began to improve and at no time did he show signs of infection or extravasation. No cystoscopic examination was made, but later a functionless kidney was found by the urologist, absolutely no urine coming from the ureter, the ureter being closed at its junction to the pelvis of the kidney. It was therefore assumed that the ureter was injured at the time and in healing had closed completely and thus an auto-nephrectomy had occurred, the result a functionless kidney.

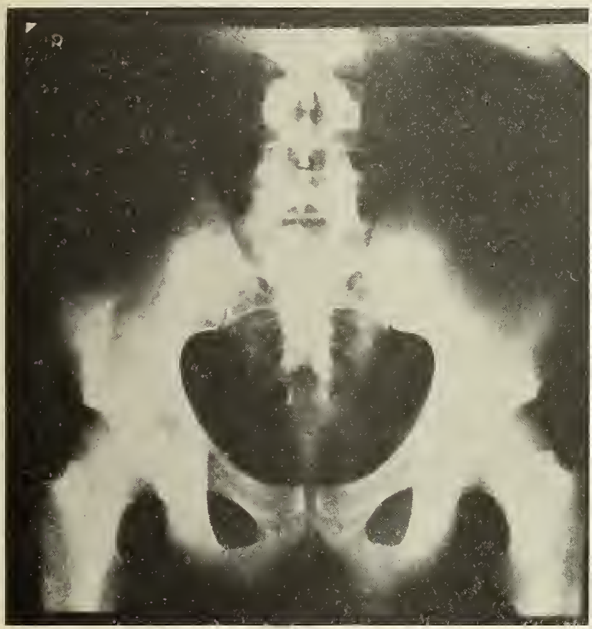

Fig. 3. Case 7.—A. L. Fracture of the right crest of the ilium; fracture of the twelfth rib on the right side with injury to the right kidney and ureter.

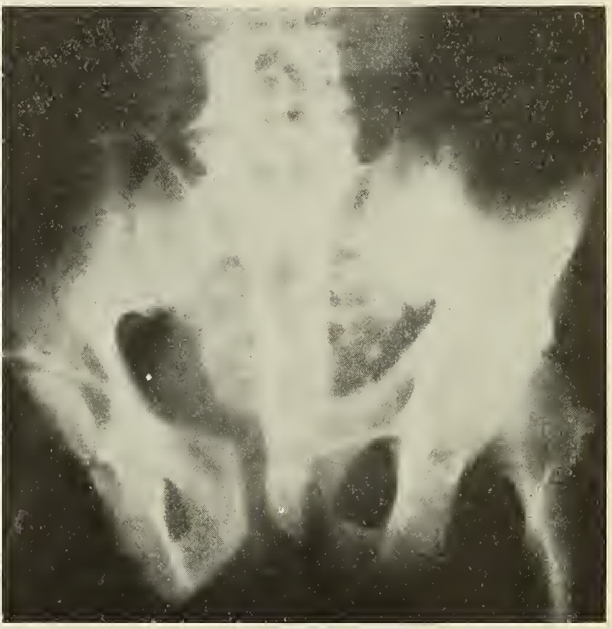

Fig. 4. Case 9.—A. S. Compound fracture of the right crest of the ilium with displacement; separation of the symphysis pubis; separation of right sacro-iliac joint. Blood in the urine.

The principal symptoms of rupture of the kidney are hematuria, pain and a mass in the region of the kidney. The mass is usually due to the bleeding from the kidney. The rapidity with which it increases in size gives a rough estimate of the severity of the kidney hemorrhage. When the kidney is injured, such as in contusion or rupture, the question arises as to what other organs have been injured, if any, and whether or not the kidney injury demands operative treatment. After ruling out injury to the urethra and bladder, the two outstanding indications for operation are hemorrhage and infection. In the period immediately following the injury, one seeks, especially, any evidence pointing to severe and continuing hemorrhage. Repeated examinations of the blood pressure, hemoglobin and counts of red and white cells of the blood are of assistance in determining the continuance of hemorrhage, as stated in Dean Lewis's Surgery. Drainage for infection of hematoma or extravasation of urine into the lumbar gutter, and suture of the kidney or nephrectomy for control of hemorrhage, are the usual operative procedures when operation is decided upon.

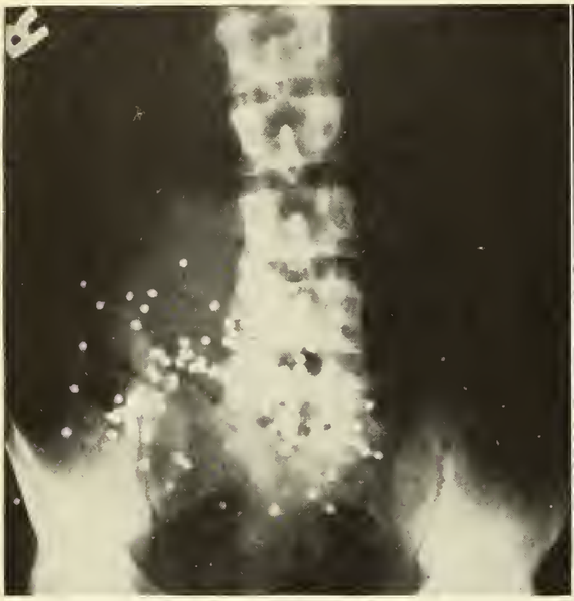

Fig. 5. Case 14.—M. B. Gunshot fracture of the pelvis: Fracture of the left ilium—injury to sacro-iliac joint; fracture of two transverse processes of the lumbar vertebræ.

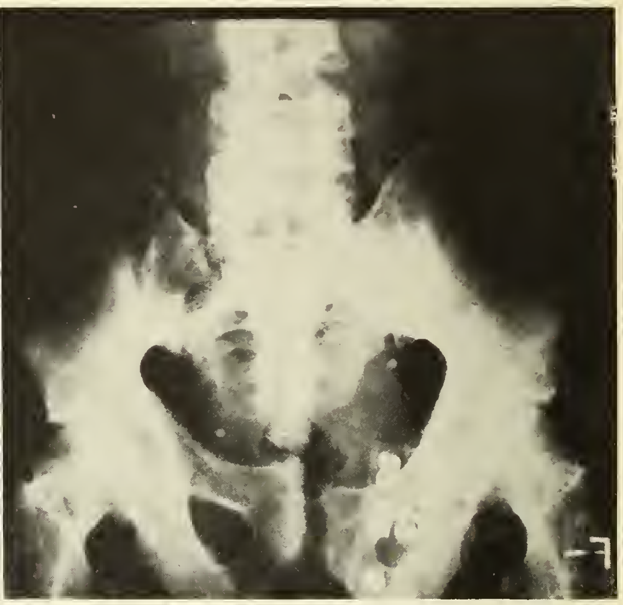

Fig. 6. Case 15.—G. J. Separation of the symphysis pubis; separation of the right sacro-iliac joint. Traumatic asphyxia.

Bellevue Hospital, New York City, reports from 1914 to 1929 fifty-two cases of kidney injury, complicated in only one instance by pelvic fracture. Of these fifty-two cases, twenty-eight were simple contusions; six of these were operated on and all got well. There were eighteen cases designated as laceration or rupture of the kidney. The mortality record shows the seriousness of kidney injury as a class. Eighteen of the fifty-two patients (34.6 per cent) died; thirteen died without operation; five died following operation. Of the eleven cases operated on for contusion or rupture, six lived. Nephrectomy was done five times. There is probably no fixed rule to follow in these cases. Each case must be treated on its merits. The surgeon should stand ready to do an exploratory operation in the presence of alarming or continued hemorrhage in an effort to control it. Kidney suture or nephrectomy may be required.

Following the treatment of the complications of pelvic fractures, the patient should be placed in bed and treatment of the fracture itself begun. In most of our cases, this was done by simple rest in bed flat on the back, using sandbags for support to the legs and pelvis. In some of the cases, we have used, in addition, traction with abduction, especially if there was upward displacement; and an encircling belt which could be tightened gradually, especially in sacro-iliac and symphysis pubis separations. Adhesive strapping was also employed.

We have used the plaster cast in only one case, in which the acetabulum was fractured, and in this case traction was employed previous to the application of the cast. This had to be removed as it was not satisfactory and traction again resorted to with suspension of the leg. We did not operate on any of our cases. In one case in which there was bad displacement of the fragment of the horizontal ramus of the pubis we felt that a better anatomical result might have been obtained by operative replacement, but functionally the result is good. At present we are using a fracture bed with overhead frame which allows extension in all directions and also overhead suspension. It has also a trundle-bed arrangement for raising and lowering the patient for use of a bed-pan, caring for the patient's back and other necessary nursing care without necessitating turning or lifting or disturbing the patient in any way or moving the extension or fractured parts, the patient being suspended by canvas cross pieces. We feel that this is very valuable in the treatment of pelvic fractures, fractures of the spine, fractures of the neck of the femur and all other femur fractures. Of course, the bed can be used in any fracture that requires extension and rest in bed.

Noland and Conwell, who recently reported 125 pelvic fractures in their work with the Tennessee Coal, Iron and Railroad Company, treat their patients by an overhead pelvic suspension frame. Suspension is obtained by a canvas sling or hammock which extends from the upper third of the thighs to the lower dorsal region. We quote from them as follows:

"This hammock acts as an immobilizing factor because of the lateral compressive action on the pelvic girdle, the force being approximately equal to the body weight. This force is continually in action and as relaxation of the muscles take place there is a constant disposition of the displaced fragments to fall into their natural position. As a general thing, marked relief of pain is noticeable within the first few hours following the application of the pelvic hammock.

"Suspension is supplemented by traction on the legs and thighs with about fifteen to twenty degrees of abduction at the hip. This relieves the marked spasm of the strong adductors, prevents scissoring of the thighs, tends to pull the fragments back into place and prevents the limited abduction so commonly observed following these injuries. Sufficient weight is used on the hammock to counterbalance the weight of the patient but not enough to raise the patient completely from the bed. Weights used for leg traction vary from four to eight pounds. A spreader is used in certain cases to prevent too great a lateral pressure by the hammock. Lateral pressure of the hammock may at once cause an overlapping at the point of the fracture unless it is offset by the intelligent use of the spreader. The degree of lateral pressure can easily be governed by the lowering or raising of the wooden spreader. The spreader should be the exact width of the individual's pelvis within the canvas sling. The use of the spreader should be routine treatment, except in cases in which a separation of the symphysis is present. In such cases a high degree of lateral pressure is necessary, and is obtained by the use of the hammock without the spreader."

Noland further states this method of treatment gives high degree of ease and comfort to the patient, greatly simplifies nursing care, prevents a certain amount of muscular atrophy, allows for improved circulation throughout the pelvis, and allows easy access for care and dressings when the soft parts have been injured. He says:

"We believe that these fractures should be treated by traction and suspension for an average period of at least forty-two days. At the end of this time, the hammock is removed and the patient is allowed to move around about in bed for another week. The pelvis belt is applied immediately after the removal of the hammock. At the end of the seventh or eighth week, the patient is allowed out of bed and begins weight bearing with the aid of crutches.

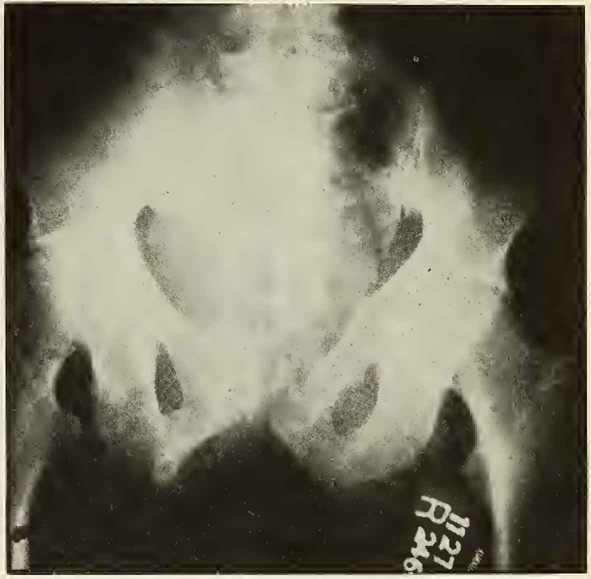

Fig. 7. Case 16.—J. N. Fracture in two places of the right horizontal ramus of the pubis; fracture of the descending ramus of the pubis; fracture of the left pubic bone through the body; fracture of the sacrum at its lower right side near the sacro-iliac joint.

As convalescence proceeds, daily hot tub baths and local heat are used. The patient should be kept under close observation for a long period. Judgment should be used in forcing these men back to work. In our early experience we were inclined to return them to work as early as possible, but frequently found that after a few days at work they were inclined to develop muscular spasm of the back and thighs, which necessitated return to bed with consequent lowering of morale. We attempt at all times to assure the patient that he has excellent prospects of recovery and that the long period of bed treatment is not because of the expectation of a permanent disability but to enable the fractures to be immobilized long enough for union to take place and healing of the soft structures."

From our own experience, the excellency of this method as outlined by Noland and Conwell appeals very strongly.

We quote from H. Winnett Orr of Nebraska, regarding his treatment of fractured pelvis, as follows:

"It is quite important in these injuries, as in most other fractures, to secure reposition of the fragments and to maintain this position during the entire period of healing. Wide abduction and traction (Whitman position) are essential because they give just the kind of pull on the attached ligaments that will draw the injured parts of the pelvis into correct position. Fixed traction in a cast is the best method for maintaining length, and, finally, a double spica cast is required to immobilize the pelvis. Our technic in such cases is as follows:

"The traction is applied when the fracture is reduced and so immobilized or fixed in immobilizing apparatus that it and the fractured extremity remain undisturbed and unaltered until at least preliminary healing has taken place. The exact technic as employed by us is the following:

"Moleskin adhesive traction straps are applied to the limb, 3 inches wide and varying in length for fractures of the leg or thigh. The frayed ends of a strong, pliable rope are sewed into the distal ends of the straps to be used for traction purposes. The straps are applied to both sides of the limb well up to the site of the fracture and bandaged into place with muslin bandage.

"The patient is anesthetized on a fracture table; traction is instituted by a muslin bandage about the foot and the rope ends are attached to the traction device by which a pull is made and continued until the limbs are of equal length. The cast is applied in the usual manner, as far down on the extremity as the ankle. After the plaster is sufficiently set, traction having been continuously maintained by the foot bandage, the traction straps are cut off from the holding device, turned back against the leg portion of the cast, and embedded in the cast by several turns of plaster bandage, thus anchoring them and maintaining traction. When the plaster is set, the muslin bandage anchoring the foot is removed, and the foot wrapped with sheet wadding, and a cast applied with the foot at a right angle to the leg. Complete recovery and ability to be up and walk about may be expected by this method in 8 to 12 weeks."

In conclusion, let us reiterate that in pelvic fractures, as in skull fractures, the treatment of greatest importance is the treatment of the injury to the important soft structures and that we must diagnose these serious injuries to important soft structures early if we are to give life saving medical and surgical treatment at the right time, and that pelvic fractures with their accompanying serious injuries to important organs and high mortality rate will continue to increase unless the industries, the transportation companies and the people themselves in driving their own automobiles do everything possible to cut down the number of accidents.

CASE REPORTS

Case 1.—J. P., male, aged 21, single, was injured April 11, 1922. He was squeezed between a motor car and was rolled against a timber in an iron mine. The injury consisted of an excoriation of both hips just below the anterior inferior iliac spines. *X*-ray showed fracture across the right ilium from the anterior inferior iliac spine to the sacro-iliac synchondrosis without displacement. He was brought to the hospital in an ambulance. He remained in the hospital until May 19, 1922, thirty-eight days. He was confined in bed flat on his back for three weeks. Sandbags were used as supports. At the end of three weeks, he was allowed to get up on crutches and walk around the ward. At the time he left the hospital, he was able to walk outdoors on crutches. He was able to do light work on August 1, 1922, being disabled 111 days. He has worked in the mine constantly ever since at his regular job, function good.

Case 2.—C. N., male, aged 36, single, was injured May 25, 1922. He was brought to the hospital in an ambulance. He was injured in an iron mine by being squeezed between two cars. *X*-ray showed the following fractures: (1) fracture through the left ilium; (2) fracture through the descending ramus of the pubis. He was put to bed in the hospital flat on his back, the pelvis supported by sandbags. He complained at first of considerable pain in the pelvic region, pain on urination, and also some pain in the abdomen in the region of the stomach. There was no blood in the urine. He remained in bed in the hospital until July 3rd, when he was allowed to get up on crutches. After that he was up nearly every day on crutches and was discharged from the hospital on July 11th, having been in forty-seven days. He returned to work on October 6, 1922, disabled 134 days. At present time, he is working in the mine at his regular work. He feels well and function is excellent.

Case 3.—F. K., male, aged 37, married, was injured June 22, 1922, by falling down a skidway and being struck by rolling logs. He was brought to the hospital in fair condition. *X*-ray showed: (1) fracture of the horizontal ramus of the left pubis; (2) fracture of the descending ramus of the left pubis. He was put to bed in the hospital flat on his back with sandbag supports. He remained in the hospital forty-two days. He returned to work in one year, with a good functional result. He has been able to work since, but sometimes has a little pain and a slight limp.

Case 4.—J. V., male, aged 35, married, was injured August 18, 1922, in an iron mine by a cave-in. The patient was brought to the hospital vomiting and in a severe state of shock. He was at once treated for shock and catheterized, very little bloody urine being obtained. The abdomen was tense and hard; rupture of bladder was suspected. *X*-ray of the pelvis disclosed the following fractures: (1) fracture of the left ala of the ilium; (2) fracture of the horizontal ramus of the left pubis; (3) fracture of the horizontal ramus of the right pubis; (4) fracture of the descending ramus of the right pubis; (5) fracture of the transverse processes of the two lower lumbar vertebræ. He also had a hematoma in the right groin and a contusion of the right thigh. After two or three hours, when there was slight improvement in his condition, he was prepared for operation and taken to the operating room. The abdomen was opened under local anesthesia. Blood and urine were found in the abdomen and an intraperitoneal tear in the fundus of the bladder, transverse and about one inch from side to side, was located. The mucosa was closed with catgut and the bladder wound closed by three rows of Lembert's silk sutures. A drainage tube was left in the abdomen down in the pelvis behind the bladder and a catheter was placed in the bladder through the urethra and secured in place. His condition was not materially worse after the operation. He failed to rally, however, after the shock of his injuries, gradually failed and died at 7:20 A. M., August 19, 1922, about thirteen hours after his injury. We did not feel that the operation in any way hastened his death.

Case 5.—J. O., male, aged 66, widower, was injured on January 25, 1923, while working in the woods, by a tree falling and striking him. He was brought to the hospital. His radial vessels were sclerotic, there was marked ecchymosis over the back and right hip posteriorly, crepitus marked over the crest of the right ilium, but no injury to the bladder, the urine being clear and normal. *X*-ray showed fracture through the crest and thin flat portion of the ala of the right ilium. He was given first aid and then sent to his doctor at his home in another town. No further history was recorded. Presumedly, he made a complete recovery.

Case 6.—E. M., female, aged 23, married, was injured on June 2, 1923, by a fall of thirty-five feet from a lookout tower. She and her husband, a forester, were in the tower when it was blown over by a windstorm. She was unable to walk but could crawl and helped her husband get out of the wreckage. He, though injured, sustaining a fractured shoulder, took a boat and went for help, leaving her alone. The accident happened at 1 P. M. They arrived at the hospital at 8 P. M. On arriving, she was put to bed and treated for some shock. It was necessary to catheterize her; the urine was examined and no blood was found. The patient was very tender over the lower abdomen. It was felt that she might have a perforation of the bladder or bowel. She did not vomit. *X*-ray picture taken showed a bilateral fracture of the pelvic bones, namely: (1) fracture of the horizontal ramus of the right pubic bone; (2) fracture of the descending ramus of the right pubic bone; (3) fracture of the horizontal ramus of the left pubic bone; (4) fracture of the descending ramus of the left pubic bone. Position was good and the patient was put to bed flat on her back and supported by sandbags. For several days following injury she had rather stormy symptoms, her lower abdomen being quite distended and

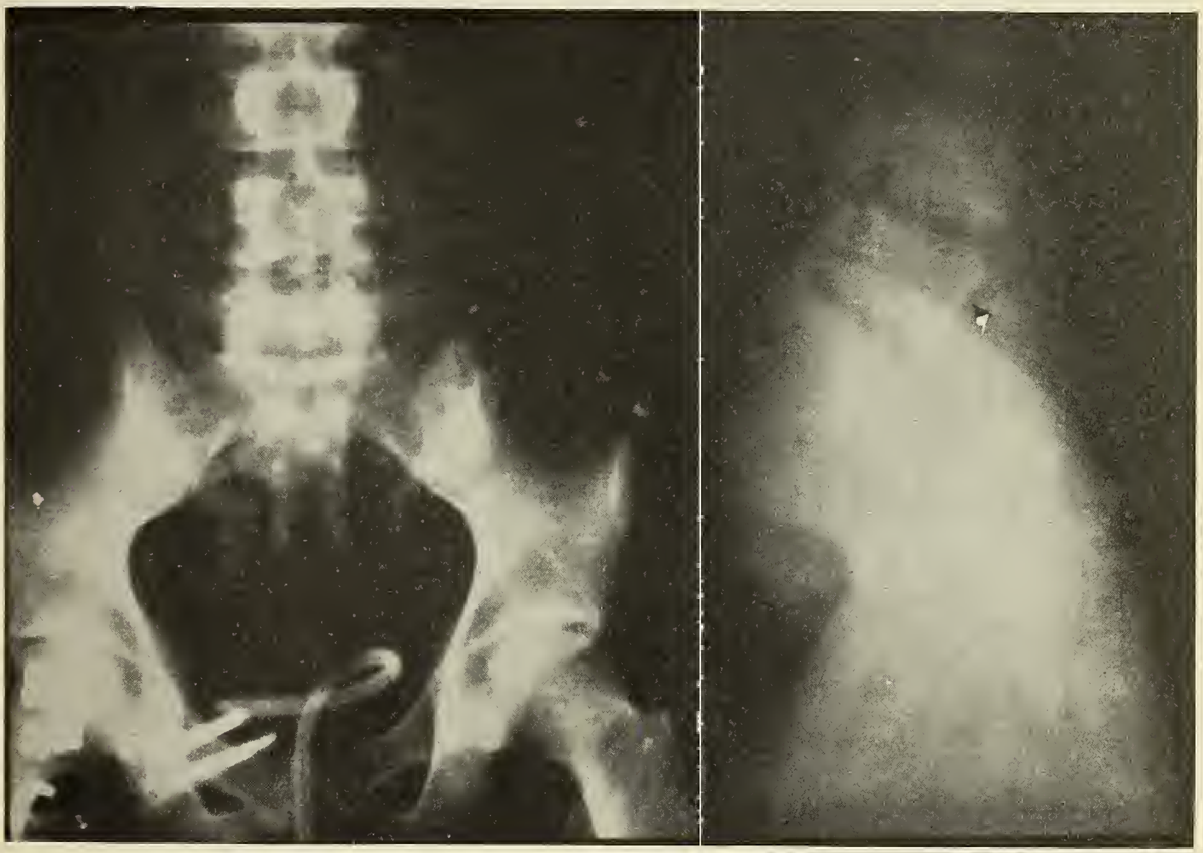

Fig. 8. Case 18.—M. R. Gunshot wound fracturing pelvis and spine with cord injury. Recovery.

very tender but not markedly rigid. She had to be catheterized several times but no blood was found in the urine. Bowel movement was obtained by enemas. Symptoms gradually subsided but there was considerable ecchymosis in the perineal region; there was also a contusion of her left ankle, but *x*-ray showed no fracture. She was sitting up a little at the time before she left the hospital July 31, 1923, after a stay of fifty-nine days. She went home and went to bed. She was at home until August 17, 1923, when she had an attack of acute appendicitis. She was brought to the hospital and operated immediately, remained in the hospital eight days. She gradually recovered and began to walk and was able to attend to her household work on November 15, 1923. At present, she is doing her household work, feels well and has no pain or disability, function excellent.

Case 7.—A. L., male, aged 19, single, was brought to the hospital September 17, 1923. He had been injured in the region of the right kidney and right pelvis by being struck by a heavy steel bar while doing construction work. The patient was pale and cold, with a rapid, weak pulse and in a state of severe shock. All movements gave him great pain. He constantly moaned and seemed unable to answer questions. An *x*-ray taken at once of the lumbar spine and pelvis showed a fracture of the right crest of the ilium and fracture of the twelfth rib on the right side; no injury to the vertebra was shown. There was a considerable tumor-like swelling on the right side in the region of the kidney and lower back. The patient was catheterized and almost pure blood was obtained. It was thought the patient had an injured kidney, probably ruptured, with hemorrhage into the bladder and tissues surrounding the kidney, and a severe contusion of the back muscles. He was in poor condition for operation and immediate operation was not thought necessary. He was put to bed and treated for pain and shock. He had a rather stormy convalescence but gradually improved. No operation was performed. Blood disappeared from the urine entirely in about a month. His injury consisted of a fracture of the crest of the right ilium, fracture of the twelfth rib, probable injury to the right kidney (rupture) and ureter, severe contusion of the right side of the back, kidney region and lower back. He was up in a chair on October 24, 1923, walked about on crutches on November 2nd and left the hospital November 9th, being in the hospital for a period of fifty-eight days. Finally, he recovered with some deformity of the crest of the right ilium and a functionless kidney as reported by cystoscopic examination by a urologist. He is now working on the surface at the iron mines doing regular work, is well and healthy, does not complain of any pain or difficulty, walks well, has since married and has one child.

Case 8.—A. H., male, aged 47, single, was brought to the hospital April 29, 1924. He had been injured in an iron mine by being squeezed between a car and a post. He was in a bad state of shock. Examination showed severe contusion of the chest with traumatic asphyxia, his face being purple and eyes bloodshot. *X*-ray showed fracture of five or six ribs with considerable displacement and fracture of the left scapula with some displacement, fracture of the descending ramus of the pubis with no displacement. It looked as though he would live only a few hours. His pelvic injury was not nearly as serious as his chest injury. There was no blood in the urine. The first treatment was directed toward saving his life rather than attempting in any way to replace the broken bones. He gradually improved after a stormy convalescence. He left the hospital June 9, 1924, being able to walk on crutches, after forty-two days in the hospital. His back was very weak. He began light work March 9, 1925, being disabled 313 days. He went to his home in Finland, never quite fully recovered so that he could do his former work. The chest injury was the cause of this disability and not the pelvic fracture.

Case 9.—A. S., male, aged 54, married, was injured in an iron mine September 3, 1925. While stealing a ride in a tram car, he was struck by an overhanging chute. He was brought to the hospital in a state of shock, with considerable bleeding from an external wound over the right crest of the pelvis. *X*-ray showed the following: (1) compound fracture of the right crest of the ilium with displacement; (2) separation of the symphysis pubis; (3) separation of right sacro-iliac joint. Catheterization showed bloody urine. During the first week, he had to be catheterized at times and at times passed urine, usually with blood. The urine gradually cleared. Bleeding was probably due to the mucous membrane injury of the bladder and possibly other portions of the genito-urinary tract. He was treated by being placed flat on his back in bed and as soon as he was over his shock a wide canvas belt with buckles was applied, extending over the trochanters of the hip and brought together gradually by tightening up daily to bring the pubic bones in apposition and support the sacro-iliac joint. Fairly good apposition and position was obtained. He was in the hospital from September 3 to December 12, 1925, a total of 100 days. He commenced to move around some and walk on December 5th. At present he is alive and well and is working in the mine as a bell ringer. Before the injury he was a trammer. He started light work September 7, 1926. He complains of pain at times in the perineal region. He has had some permanent partial disability.

Case 10.—W. R., female, aged 39, married, was injured November 29, 1925, in an automobile accident. She was brought to the hospital semiconscious, cold and clammy, with a very weak pulse and in a state of shock. She had a large scalp wound on top of her head with considerable undermining of the tissues. The scalp wound was opened and explored; no skull fracture was found. There was concussion of the brain. She had a double fracture of the right clavicle, a small central piece about two inches long being entirely broken out and dislocated as shown by *x*-ray. She had numerous bruises over the body and an injury in the region of the right hip and pelvis. *X*-ray taken of lumbar spine, pelvis, and hip showed fracture of the right ramus of the ischium, but no displacement. She passed blood in the urine for a week or ten days. The patient was put to bed in the hospital flat on her back and kept quiet. She recovered from the shock and went to her home on a stretcher December 8, 1925, having been in the hospital eight days. She was put to bed at home and remained in bed three months and then started to walk. At the end of four months, she began housework. She is now feeling well and has no trouble from the injury.

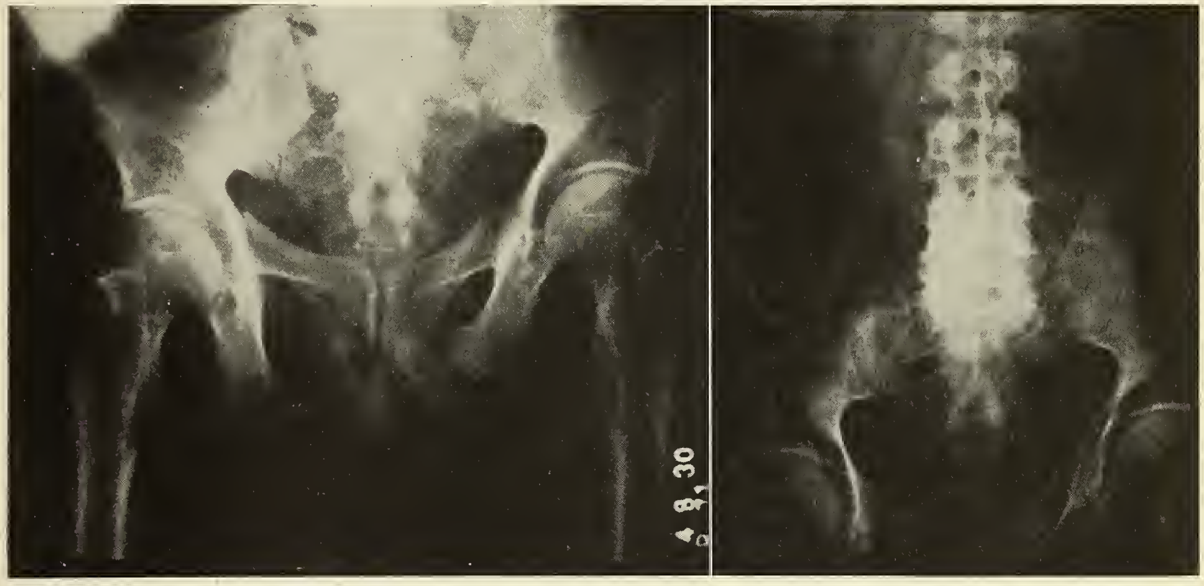

Fig. 9. Case 19.—J. S. Fracture of the horizontal ramus of the left pubis at its outer end and also at its inner end; fracture of the body of the left pubic bone; fracture of the descending ramus of the left pubic bone; fracture of the horizontal ramus of the right pubic bone at the outer end; fracture of the descending ramus, right pubis; some separation of the left sacro-iliac joint; fracture of the transverse processes of the lumbar spine. Death in three hours.

Case 11.—M. D., male, aged 28, married, was injured December 15, 1925, in an iron mine by being squeezed between a car and timber. The injury consisted of only a simple, irregular fracture of left ilium without displacement. He was put to bed in the hospital flat on his back with adhesive strapping of the pelvis. He left the hospital December 24, after nine days in the hospital. He went to his home to remain in bed. He was able, however, to walk around with crutches. January 25, 1926, he was walking with one crutch, but had some pain when walking. By February 8, 1925, he was doing well, walked without crutches but with a limp. April 5, 1926, he returned to work at the mine on light duty. At present he is well and healthy, doing a regular miner's work, with no pain or trouble from the fracture. He remained at home for a total of 110 days.

Case 12.—H. M., male, aged 46, single, was brought to the hospital, having suffered an injury in an automobile accident September 29, 1926. He complained of pain in the chest, difficulty in breathing, and his eyes were bloodshot and his face blue, somewhat like a traumatic asphyxia. He also had a pelvic injury. *X*-ray showed fracture of the descending ramus of the right pubis. He was put to bed in the hospital for a period of ten days, when he was allowed to go home and remain in bed. After he went home, he was in bed most of the time but sat up every day. Finally he began walking and went to work about four months after the injury. At present he is working in the mine and has no trouble nor disability.

Case 13.—R. G., male, aged 29, married, was injured April 4, 1927, by being squeezed and rolled between cars and timber in a mine. He was brought to the hospital in great pain and in some shock. *X*-ray showed fracture of the right ilium extending from the crest well down into the bone. General position was good. There was a large hematoma over the site of the injury. He was put to bed in the hospital, treated for mild shock, and sandbags were placed along the side of the pelvis and leg for support. The position of the fragments seemed good and no attempt was made to improve it. The patient did well in the hospital and was discharged April 26th, having been in the hospital twenty-two days. He was walking on crutches when he left. He was discharged for work July 6, 1927. At present he is working in the iron mines and has no trouble whatever.

Case 14.—M. B., male, aged 22, single, while out hunting November 27, 1927, was accidentally shot by the discharge of his companion's gun. He was brought to the hospital in a state of shock. Examination showed a young, healthy, robust man. He had lost considerable blood but his pulse was fair. He was in considerable pain, and a large gunshot wound was evident about 3 inches from the lower lumbar spine and 1 inch above the ilium in the left loin. *X*-ray showed a large number of shot buried and a fracture of the left ilium near the crest extending down to the sacro-iliac joint; also two transverse processes of the lower lumbar vertebræ fractured. The wound was cleaned up. Large numbers of shot, paper wads and other foreign material were removed. As there was considerable bleeding, the wound was packed with iodoform gauze. Patient was given 1,500 units of anti-tetanus serum and put to bed in the hospital. He had a rather stormy convalescence on account of considerable infection and some osteomyelitis with losses of pieces of bone. He left the hospital at the end of 70 days. When he left, he was able to walk. He came in for a long period of time for dressings. He started work May 1, 1928, having been disabled 154 days. He had an operation September 1, 1929. A large piece of bone was removed. Since then the wound has completely healed, and he is able to do any kind of work.

Case 15.—G. J., male, aged 47, married, was injured December 8, 1927, in an iron mine by a car of ore dumping over on him. He was brought to the hospital in a state of shock. He was a large muscular man and an old miner. Examination showed injury to the pelvis and a ruptured bladder was feared. He also had a traumatic asphyxia. His face was very much swollen and purplish in color. This extended down to the neck and upper part of the chest, especially to the front. He had some small hemorrhages under the skin and in the conjunctiva of the eyes. The pulse was fair. His greatest complaint was of pain in the pubic region. *X*-ray of the pelvis and lower dorsal and complete lumbar region showed nothing in the spine but a separation of the symphysis pubis and of the right sacroiliac joint. The urine was a little smoky, had some red blood cells, a large amount of albumin, and gave a reaction for blood by the guaiac test. The bladder was filled with sterile boric acid solution and the full amount of fluid was returned. It was therefore felt that he did not have a ruptured bladder. The following day, the urine was clearing, was not so smoky and did not contain so much albumin. The urine gradually cleared up; no gross blood was seen at any time. The pubic bone was displaced upward on the right side. He was treated by extension traction and a wide belt placed around the trochanters with buckles tightened up gradually. He remained in the hospital until April 14, 1928, making a total of 128 days. At that time he was able to walk around with crutches. He began light work February 18, 1929, and has since continued to work.

Case 16.—J. N., male, aged 46, single, was injured by being struck by an automobile November 23, 1928. He was brought to the hospital. *X*-ray taken at once showed the following fractures of the pelvis: (1) fracture in two places of the right horizontal ramus of the pubis; (2) fracture of the descending ramus of the pubis; (3) fracture of the left pubic bone through the body; (4) fracture of the sacrum at its lower right side near the sacro-iliac joint. Position of the fragments was good except that there was a jamming down and impaction of the right horizontal ramus, which had been fractured in two places. This jamming down was at the pubic end. This patient was in good condition. There was no blood in the urine. There was considerable extravasation of blood in the tissues. Patient was placed flat in bed on his back and supported by sandbags. On January 5, 1929, he was able to walk and was allowed to go to the home of a friend, staying in the hospital 43 days. He returned to light work in about seven months or 210 days. At present he is working daily in an iron mine. He says that his pelvis does not feel quite secure and firm. There is considerable displacement of the fragment of the right horizontal ramus with some palpable deformity. This fragment possibly should have been operated on for better replacement.

Case 17.—S. W., male, aged 48, married, was injured March 9, 1929, by a cow jumping on him and knocking him down. He was brought to the hospital in good condition. *X*-ray showed fracture of left acetabulum with displacement upward of the head of the femur and about 0.5 inch shortening. He was put to bed in the hospital with traction, suspension and abduction. He later developed a foot drop, which, however, entirely cleared up. It was doubtless due to peroneal nerve injury. He remained in the hospital until May 4, 1929, a total of 56 days, when he was taken to his home and put to bed and extension reapplied. May 21st all extension was removed. The patient was in bed for a week, until May 29, 1929, when a walking caliper was applied. On July 9th the caliper was taken off; movements were excellent in all directions and there was about 0.5 inch shortening. At present time he is doing well, still limps some and walks with a cane.

Case 18.—M. R., male, aged 22, single, was accidentally shot July 30, 1929, and was brought to the hospital. It was found that a bullet had struck him on the right side about the region of the brim of the right ilium pretty well back, the bullet coming out on the opposite side. He lost considerable blood and was in poor condition. *X*-ray of the pelvis and lower spine region taken antero-posteriorly showed fracturing of the right ilium and lead scattered along the course of the bullet with injury to the spinous processes and laminæ of the fourth and fifth lumbar vertebræ. A lateral *x*-ray picture showed the same fractures. There was evidently some cord injury, as he was unable to empty the bladder and he had loss of power in his legs, although he was able to draw them up and move them quite well. The abdominal and cremasteric reflexes were present and sensation was present in both legs and feet. There was no reflex of the toes and he could move them only slightly. He remained in the hospital until August 10, 1929, when he was allowed to go to his sister's home. During the time he was in the hospital, he improved gradually. He was able in a few days to void and began to walk around on crutches after he went home. There was considerable infection of the wound and pieces of dead bone were removed at times. When last heard from he was walking with a cane and there was some discharge from the wound. He was seen June 14, 1930, when he could walk well using a cane but not without it. No knee jerk could be obtained. The wound was completely healed. He thinks he will be able to work after a while.

Case 19.—J. S., male, aged 47, married, was injured April 8, 1930, by falling into a car and being struck by some ore. The patient was in a state of severe shock. *X*-ray showed: (1) fracture of the horizontal ramus of the left pubis at its outer end and also at its inner end; (2) fracture of the body of the left pubic bone; (3) fracture of the descending ramus of the left pubic bone; (4) fracture of the horizontal ramus of the right pubic bone at the outer end; (5) fracture of the descending ramus, right pubis; (6) some separation of the left sacro-iliac joint; (7) fracture of the transverse processes of the lumbar spine. The patient was in such a severe state of shock that he soon died, living only a little over three hours. No postmortem was done and it was not known what internal injuries he may have had, such as ruptured bladder, bowel or blood vessels.

THE MANAGEMENT OF OPIUM ADDICTION

Many of the so-called specific cures have been given fair trial by critically minded observers, but the results have been consistently unconvincing. This applies to rationally conceived proposals as well as to exploited products like "Narcosan" or the alleged secret Kahle treatment discussed in the German medical press. The conclusion of a British reviewer seems to be justified that it is now realized more thoroughly than ever before that the major problem is not to free the addict from his drug but to keep him free. Morphine addiction is not characterized by physical deterioration or impairment of physical fitness. Herein lies the hope that rehabilitation by any process may be satisfactory so far as the physiologic functions are concerned. The mental and psychologic problems are not yet so easily disposed of. Relapse is common to all methods of treatment and the question as to whether the withdrawal of the alkaloid should be gradual rather than abrupt may be discussed in the light of many reports. British opinion, with a few notable exceptions, seems to be in favor of a reduction treatment as the routine method of cure. (Jour. A. M. A., September 13, 1930, p. 801.)

INTOXICATING EFFECT OF ACETYLSALICYLIC ACID AND COCA-COLA

A physician reports that young people in his community are using from 15 to 20 grains of acetylsalicylic acid (aspirin) dissolved in the soft drink, Coca-Cola, as an intoxicating beverage. The effects are due chiefly to central depression caused by the acetylsalicylic acid fortified possibly by a direct central stimulant action of caffeine and other constituents present in Coca-Cola. The actions of acetylsalicylic acid are similar to those of small doses of alcohol, or of a weak alcoholic beverage or of the barbitals or bromides. When acetylsalicylic acid is taken with a beverage like Coca-Cola, advertised for its exhilarating effects, which may be caused by a direct central stimulation by caffeine or other constituents of the latter, it is easy to see how the effects of one can be fortified by the other. The continued use of such a medicated beverage may result in undesirable effects of the same general nature as those of narcotic habituation. Here is a most insidious evil, the reinforcement of a popular and highly advertised beverage by a well advertised drug, both long suspected of dangerous tendencies. (Jour. A. M. A., November 1, 1930, p. 1366.)

SEROTHERAPY OF MEASLES AND POLIOMYELITIS

Chester A. Stewart, M.D., Ph.D., and Erling S. Platou, M.D.
Assistant Professors of Pediatrics, University of Minnesota
Minneapolis

THE annual death rate from measles is undoubtedly sufficiently high to warrant active efforts to accomplish its reduction. According to a report from London, measles during the past thirty years has become a more serious menace to life than scarlet fever, the former disease being responsible for a mortality rate of 251 per million as compared with 42 per million from the latter. In childhood, measles is responsible for about six per cent of deaths under three years of age, and for about 2.4 per cent of deaths during the first ten years of life. The mortality rate from measles may become exceedingly high following its appearance in communities which have been free from the disease for a number of years. This was illustrated by the epidemics which have occurred in certain Islands where the death rate has exceeded 25 per cent of the population. The serious potentialities of measles epidemic illustrate that such outbreaks cannot be viewed with complacency and emphasize the need of developing effective prophylactic and therapeutic measures.

For a number of years the contagium of measles has been known to be present in the blood, and also in the buccal and nasal secretions, particularly during the pre-eruptive and early stages of the disease. Attempts to isolate and identify the causative organism have not produced conclusive results, although these investigations have been conducted over a period of more than sixty years by many careful workers. During recent years the attention of investigators has been directed particularly toward the identification of either a filterable virus or a micrococcus as the possible cause of measles. Those who favor the micrococcus concept as the causative factor of measles (Ostrovsky ('97), Tunnicliff ('17), Caronia ('23), Cory and Day ('27) and others) however, apparently are individually considering somewhat dissimilar organisms falling in the group, and among themselves are unable to agree upon any one of these different strains of cocci as the sole and true etiology of measles. The demonstration that certain micrococci can be isolated from the blood of patients having this disease no doubt is of importance, but does not necessarily constitute proof that they are the etiologic agent.

Opposed to those who favor the micrococcus theory, there are a considerable number of investigators who consider a filterable virus to be the cause of measles. Those supporting this opinion include Hektoen ('05), Blake and Trask ('21), Degkwitz ('27) and others. To date, however, this filterable virus has not been isolated in pure culture.

At present one must feel that the etiology of measles is still disputed, and conclude further that the use of the various anti-measles sera for therapeutic, prophylactic and attenuating purposes other than convalescent or adult immune human serum probably should not be recommended for general use until more conclusive evidence is presented that the causative agent of measles has been definitely isolated, and that the various artificial sera are producing more constant results than have been reported in the literature.

THERAPEUTIC USE OF SERUM

The therapeutic administration of anti-measles serum is desirable in certain instances, particularly when the disease develops in a malignant form, and also when it arises as a complication of some previously existing acute and serious illness. Under such circumstances the administration of convalescent serum is of value in alleviating the severity of the disease and shortening its course. The first therapeutic use of convalescent serum was reported by Weisbecker in 1896. Since then Majoli ('15), Ribadeau-Dumas and Brissaud ('18), Terrien ('19), Maniel ('22), and others have employed the serum therapeutically with apparent benefit. Recently the production of animal anti-measles serum has been attempted, particularly by Tunnicliff and Hoyne ('26), but to date its therapeutic value is not sufficiently well established to justify recommending its general use. For the present, therefore, the general therapeutic use of anti-measles serum should be limited to the administration of either convalescent serum or immune adult blood in rather large amounts as early in the course of the disease as possible.

PROPHYLACTIC USE OF ANTI-MEASLES SERUM OR PASSIVE IMMUNIZATION

The effectiveness of convalescent serum in the prevention of measles was first demonstrated by Cenci ('07), and since that time by numerous investigators, including Nicolle and Conseil ('18), Degkwitz ('20), Zinger ('24), Toomey ('26), Park and Freeman ('26), Bivings ('27), Boder ('29), Van Cleve ('30), Barenberg, Lewis and Messer ('30), and others. About 5 c.c. of serum collected between the tenth and ninetieth day of convalescence is sufficient to protect a young child. The passive immunity conferred in this manner, however, lasts only a few weeks. As pointed out in the bulletin of the New York Department of Health for January 25, 1930, "there are grave objections to any method which will entirely prevent measles passively, for this would lead to the gradual building up of a large population of non-immunes which would be decimated should the disease perchance be reintroduced." In communities that have been free from measles for years, and thus made up entirely of non-immunes, the disease is apt to develop a malignant form when newly introduced. For example, Panum ('27), reported that the appearance of measles in the Faroe Islands after the absence of the disease since 1781, resulted in 6,000 cases out of a population of 7,872. Also when measles was first introduced into the Sandwich Islands in 1775, within four months 40,000 of a population of 150,000 died. Likewise the introduction of measles in the Fiji Islands in 1874 resulted in the death of 20 per cent of the population.

Prophylactic use of convalescent measles serum, therefore, probably should be limited largely to prevent epidemics in institutions, or to prevent the development of the disease in weak and debilitated children in whom the occurrence of measles superimposed upon conditions previously existing might prove fatal. When the passive immunity is desired, the administration of 5 to 10 c.c. of serum collected in the first three months, and preferably in the first two or three weeks of convalescence is recommended. The serum should be given during the first four days after exposure, and repeated in twelve days (Barenberg, Lewis and Messer ('30)), if subsequent exposure seems probable. Aside from these special instances anti-measles serum probably should not be employed prophylactically, for the immunity conferred in this manner lasts only a short time and merely defers the date when the child will have the disease. When convalescent serum is not available, adult immune serum may be administered in larger amounts (60 c.c.).

THE ATTENUATION OF MEASLES BY IMMUNE SERUM

The greatest service physicians can render in the control of measles probably lies in the employment of measures which attenuate the disease rather than those that prevent it. In this manner a lasting immunity is developed by the patient from a mild attack of measles. This may be accomplished in a very practical and simple manner, through the administration of adult immune whole blood to the exposed children.. According to the recommendation of the New York Board of Health, the blood should be obtained from the parent who has had measles and given intramuscularly, a procedure which does not require blood grouping. The dosage recommended for children under five years of age is 30 c.c., and double that amount for older patients. This permits the patient to develop a lasting immunity to the disease from a mild or attenuated complication-free attack of measles.

POLIOMYELITIS

Acute anterior poliomyelitis at first is an acute generalized systemic infection tending in the course of a few days to invade the central nervous system, following which the dreaded paralysis frequently occurs. In general there are three types of the disease, namely: the abortive, the non-paralytic and the paralytic type. In the abortive type it is assumed that the disease stops at some point in its development, failing for some unknown reason to proceed to localization in the central nervous system. Some feel that such abortive cases of poliomyelitis are very prevalent, and that consequently the majority of adult individuals have obtained an active immunity to the disease from mild attacks of this character. Since the diagnosis of the abortive type of the disease is based solely on symptoms, its prevalence remains largely a matter of conjecture. In cases where an invasion of the central nervous system occurs as demonstrated by physical signs and lumbar puncture, subsequent paralysis may or may not appear. This permits one, therefore, to recognize the clinically well established paralytic and non-paralytic forms of the disease, which unfortunately are indistinguishable at the outset. The physician, consequently, is compelled to administer serum for all cases of poliomyelitis recognized in the pre-paralytic stage. Since the serum must be given early in the disease if paralysis is to be prevented, the diagnosis of poliomyelitis in its pre-paralytic stage is of great importance.

At the onset the patient develops a fever, headache, and variable gasto-intestinal symptoms, including vomiting and diarrhea or constipation. The prostration seems to be greater than the temperature, which is usually under 102 F, would warrant. Although the general symptoms are fairly constant, they are not sufficiently characteristic to permit a recognition of the disease. A diagnosis of pre-paralytic poliomyelitis, therefore, must be made on the basis of the physical signs, which fortunately present a fairly uniform and significant picture in the early stage. One observes that the face is flushed except for the frequent presence of a definite circumoral pallor. In addition the throat is mildly reddened, and the pulse is usually accelerated out of proportion to the elevation in temperature. The remaining physical findings are limited practically to those which have to do with the nervous system. The patient may present varying degrees of hyperesthesia and slight clouding of the consciousness together with manifesting rather coarse tremors in certain instances. Of particular importance is the presence of a rigidity of the spine, which differs somewhat from the rigidity noted in meningitis. In infantile paralysis the head usually is not retracted, and although the neck is slightly rigid the rigidity seems to involve particularly the lower cervical, thoracic and lumbar rather than the upper cervical region. Thus in poliomyelitis the patient can usually flex the head on the neck at the atlanto-occipital joint, but is unable to bend the neck forward. As a result the head can be brought about half-way forward before resistance and pain are encountered. A general rigidity of the spine is a more constant and characteristic feature than stiffness of the neck. The spinal rigidity is so pronounced that in a sitting position the patient is unable to bend the head and trunk downward toward the knees. If the child bends forward at all, the flexion occurs almost entirely at the hips, while the spine remains straight and rigid. The deep reflexes are usually hyperactive in the pre-paralytic stage of the disease, and Kernig's sign as a rule is negative. The above signs require the performance of a spinal puncture in order to complete the diagnosis. The fluid obtained is usually under an increased pressure, and presents a very slight opalescence. The cell count usually ranges between 30 and 300, with the polymorphonuclear leukocytes predominating in the early stage of the disease. The polymorphonuclears, however, rapidly undergo a cytolysis, so that in a few days the cells are largely lymphocytes. In addition the globulin content of the spinal fluid is increased.

On the basis of the symptoms and physical findings as outlined above a diagnosis of pre-paralytic poliomyelitis probably is justified, particularly when care has been taken to exclude such conditions as meningismus, tuberculosis, lues, and lethargic encephalitis, conditions which might simulate infantile paralysis.

TREATMENT

The serum therapy of poliomyelitis has been limited largely to the administration of immune human serum. Rosenow ('30) has developed an anti-streptococcic serum for this purpose, and reports favorable results from its use. The outcome of pre-paralytic cases of poliomyelitis with respect to mortality and paralysis is so variable as to render it difficult to properly evaluate the efficacy of therapeutic measures instituted in such cases. This normal variability of the course of the disease in different individuals, therefore, has made many investigators skeptical of the alleged value of Rosenow's preparation. With regard to immune human serum there is apparently more unanimity of opinion as to its therapeutic effectiveness. Animal experiments have shown that convalescent serum neutralizes the virus of poliomyelitis and renders it innocuous, and also that the intrameningeal injection of the serum as late as twenty-four hours after the intracerebral injection of the virus prevents the development of paralytic disease. In addition beneficial results following the administration of immune human serum in the early stages of the disease occurring in man has been reported by a considerable number of investigators. For the present, then, the use of convalescent human serum is recommended for therapeutic purposes. The serum preferably should be administered as early in the disease as possible, giving 20 to 30 c.c. intraspinally and 50 c.c. intravenously or intramuscularly. If necessary the entire dosage may be given intravenously, although it is probably more advisable for a certain amount of the serum to be given intraspinally. Favorable results have been reported by Shaw and Thelander ('28) even from the intramuscular administration of the serum. Although the best results are obtained where the serum is given in the preparalytic stage of the disease, one should not hesitate to administer it after paralysis occurs, attempting thereby either to prevent a further extension of the paralysis or to promote as complete a recovery as is possible to obtain.

In the presence of severe outbreaks of epidemic poliomyelitis, convalescent human serum may be used to afford passive protection to children exposed to the disease. Although the optimum amount of serum to be used for prophylactic purposes has not been definitely established, Flexner and Stewart[28] suggest a subcutaneous dosage of 10 c.c. for young children and 20 c.c. for older children and adults. A repetition of the injection at the end of four to six weeks is suggested, should the epidemic outbreak become severe and endure for several weeks.

The main objection to the use of convalescent human serum for therapeutic and prophylactic purposes is the difficulty of obtaining it. Partly for this reason it probably will be used more generally at times when there are a considerable number of cases of the disease appearing in a community, rather than when the outbreaks are limited to sporadic instances.

At present there is little to be said concerning active immunization in poliomyelitis, aside from calling attention to the fact that monkeys have been rendered immune to the disease through intradermal injection of the virus.

SUMMARY

1. Convalescent serum or immune adult blood when used in rather large amounts may be administered beneficially for therapeutic purposes in instances where measles develops in a malignant form, and also when it arises superimposed on some previously existing acute and serious illness.

2. For prophylactic purposes the use of convalescent measles serum probably should be limited largely to prevent epidemics in institutions, and also to prevent the development of the disease in weak and debilitated children. Five to ten c.c. of convalescent serum should be given within the first four days after exposure. When convalescent serum is not available, adult immune serum may be used, but should be given in rather large amounts.

3. The greatest service physicians can render in the control of measles involves an attenuation of the disease, thereby permitting the patient to develop a permanent immunity to measles from a mild complication-free attack. This may be accomplished by using immune adult blood, giving 30 c.c. intramuscularly to children under five years, and double that amount to older patients.

4. When dealing with poliomyelitis the therapeutic administration of convalescent human serum, preferably in the pre-paralytic stage of the disease, is recommended. For this purpose give 20 to 30 c.c. intraspinally together with 50 to 75 c.c. intravenously. Furthermore, one should not hesitate to administer the serum after paralysis occurs, attempting, thereby, either to prevent a further extension of the paralysis or to promote as complete a recovery as possible.

5. In the presence of severe epidemics convalescent serum may be used to afford passive protection to exposed children, giving 10 c.c. subcutaneously to young children, and double that amount to older patients. A repetition of the injection at the end of four to six weeks is suggested should the epidemic outbreak continue in severity for several weeks.

SODIUM 2-OXO-5-IODO-PYRIDINE-N-ACETATE (INTRODUCED AS UROSELECTAN)

The Council on Pharmacy and Chemistry publishes a preliminary report on sodium 2-oxo-5-iodo-pyridine-N-acetate (also designated as sodium-5-iodo-2-pyridon-N-acetate), a new substance for use in the radiographic visualization of the urinary tract which was introduced under the name Uroselectan. The Council reports that the product is a definite chemical substance which promises to be an advance in the radiographic visualization of the urinary tract, though its indications, advantages and limitations are at the present time not fully established. The Council considers the product suitable for experimental use by those who are versed in the technic of urologic examinations. It publishes a concise and carefully considered statement of the introduction of the drug and the evidence for its use, prepared for the Council by Drs. Braasch and Bumpus. (Jour. A. M. A., November 8, 1930, p. 1425.)

THE ETIOLOGY OF GINGER PARALYSIS

Within the past year a peculiar form of paralysis has afflicted many persons, particularly throughout the Midwestern or Southwestern states. Evidence has accumulated that the malady is closely associated with the drinking of fluidextract of ginger. The latter has been sold extensively since the introduction of the Volstead Act, for beverage purposes, because of a ruling of the Prohibition Bureau to the effect that the official fluidextract of ginger is a non-potable beverage, thus removing the restriction from its sale. It was concluded from the evidence that an adulterated and poisoned product was being circulated last winter. An investigation was undertaken by the United States Public Health Service and this has shown that the paralysis was caused by tricresyl phosphate present in some fluidextracts of ginger as an adulterant. (Jour. A. M. A., November 29, 1930, p. 1672.)

IMMUNOLOGY OF DIPHTHERIA AND SCARLET FEVER*

W. Ray Shannon, M.D.
Saint Paul

With the steady advance in the specific knowledge of disease, readaptations and readjustments of thought and action must keep pace. It is our purpose here to present an appraisal of present day opinion and practice in the specific control of diphtheria and scarlet fever.

Little need be said about the use of specific serum or antitoxin for the cure of diphtheria. It is sufficient to say that it must be used early and in adequate dosage to neutralize all of the toxin of the infection if its maximum value is to be realized. Schick recommends from 100 units per kilogram in the mild cases to 500 units in the most severe cases. It should be given all in one dose and not in small repeated doses except in cases to be mentioned later where desensitization must be carried out. Naturally rapidity of action depends upon the promptness with which the antitoxin gets into the blood stream. Therefore in the most critical cases it should be introduced intravenously. In those slightly less serious or in whom intravenous injection is impossible, intraperitoneal injection affords a more rapid means of introduction than the third way, namely, the intramuscular route. The serum should never be introduced subcutaneously, except for purposes of desensitization, because of the slow absorption by this route.

It has been common practice to use antitoxin for prophylactic so-called passive immunization in cases of actual or suspected exposure. While occasionally justifiable, modern medical practice demands that we consider the possible costs of such action. The immunity so induced lasts no more than two or three weeks, frequently subjects the patient to a discomforting serum reaction and leaves him sensitized to horse serum, thus increasing the hazards in case a future necessity might arise for the use of an antitoxin. In the great majority of cases it would be better practice to postpone the use of immune serum until careful supervision shows suspicious symptoms of the disease or until positive nose or throat cultures have been obtained. Final decision of policy in this regard must, of course, rest with the individual circumstances of each case.

Present advance in the control of diphtheria is being made mainly along the lines of active immunization by means of vaccination. The success of this procedure is made possible by the development of an easily applied test of susceptibility to the disease. This test, named the Schick test after the man who developed it, consists of the intracutaneous injection of a measured amount of diphtheria toxin (1/50 M.L.D.) contained in a suitable medium. While extreme emphasis is placed upon an exact technic in its performance by most writers, as an actual matter of fact the test has a sufficiently wide margin of safety, as demonstrated by Dudley, to be extremely valuable even in the hands of a novice. The points usually emphasized are these: that exactly the correct amount of toxin must be introduced, that it must be injected intradermally and not too deeply, and that the toxin must be of proper potency. While all of these points are important, Dudley has shown that a variation of 25% either way in the amount of toxin injected would not weaken the value of the test too greatly and that even subcutaneous injection will usually afford accurate information, though perhaps a little more difficult of interpretation. The one important requirement is that the toxin shall be of proper potency. In this respect the clinician is largely at the mercy of the manufacturer and must accept his claims, but at least the physician can use meticulous care in carrying out instructions given in the package. This is especially important as regards the promptness with which the toxin is used after dilution. It must be used within twenty-four hours and preferably within a very few hours after dilution.

Unless an individual has substances in his blood to counteract the toxin injected he will develop a characteristic inflammatory reaction at the site of the injection. This reaction is termed a positive Schick, and it will be noted unless the subject has as much as 1/30 unit of antitoxin per c.c. of serum. Approximately this amount of antitoxin in the blood is required to neutralize the amount of toxin injected and has been found by clinical experience to be sufficient to protect the individual against any ordinary contact with the disease. Hence a negative Schick reactor has this much or more antitoxin in the blood and is essentially immune.

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, Minn., July 14, 1930.

The interpretation of the Schick test offers little difficulty in the majority of cases. Dudley describes a typical positive reaction as follows: " . . . in about 24 hours, or earlier, . . . a red, almost scarlet, patch about an inch in diameter appears, which is generally elliptical rather than circular, the major axis of the ellipse being in line with the limb. In four or five days the reaction, after first becoming more intense, begins to fade and desquamate, and become covered with bran-like flakes of cracked superficial epithelium, which gives to the reaction a most characteristic appearance at the end of a week. The reaction disappears slowly, and remains evident for a month or more as a pigmented patch of variable tint. A certain amount of induration accompanies the color reaction during the active stage. Variations either way from this usual reaction may occur, on the side of more intensity up to the point where vesiculation and superficial ulceration may be present, and on the side of lesser intensity to the point where nothing in the way of pigmentation or desquamation may be observed. The former indicates increased susceptibility and the latter a partial immunity to diphtheria."

Some confusion in the reading of the tests may be met with on account of a pseudo-Schick reaction. While this reaction has certain qualities which usually identify it to the experienced, the casual observer must rely upon the duration of the inflammation for its recognition. According to Dickenson only 4.5 per cent of pseudo-Schick reactions are visible at the end of a week. Park says that pseudo-reactions constitute about 15 per cent of the reactions in this country. Thus in not more than two-thirds of one per cent of the reacting cases would the pseudo-Schick be even visible at the end of a week. If we read our tests after seven days then, in only a very small number of cases should there be any confusion and these will usually be cases in which both a pseudo and positive Schick have occurred, the so-called combined reaction.

The discovery of the Schick test has opened the way for extensive minute study of diphtheria. As a result it has been found that almost all infants are immune to diphtheria at birth and that rather rapidly during the latter part of the first year this immunity is lost. Breast feeding retards this loss of immunity. After one year of age the incidence of immunity as shown by the number of negative Schick reactions begins gradually to increase. The congenital immunity is thought to have been passively transferred to the infant before birth through the placenta and for some time later through the breast milk. The later rise is thought to be actively acquired as a result of repeated subclinical infections. Hence the number of persons exhibiting this natural immunity increases with age and directly in proportion to the existence of those factors which favor exposure such as crowded living, etc. Thus it is that those persons living in rural communities are less apt to have acquired an immunity by the time they have reached adult life.

The natural sequel of such observation was the attempted artificial production of an active immunity by means of vaccination. This has proven so successful that it is now one of the most important public health measures. It has become a moral responsibility to the medical profession so well recognized that if physicians do not accept it this important health measure will, rightly, be taken out of their hands altogether.

The preparation most widely used in this country for this purpose is a solution of diphtheria toxin partially neutralized by the addition of antitoxin. It is necessary to neutralize a part of the toxin in order that a sufficient amount may be injected to bring about an immunity reaction. Naked toxin is too toxic to be used unbuffered.

Three inoculations of 1 c.c. each are given at weekly intervals. Following these injections a gradually developing immunity appears, due to the presence of antitoxin in the blood, which by the time six months have passed will have increased sufficiently to render the Schick test negative in about 75 or 80 per cent of cases.

Positive reactors should at this time receive a second series of injections, following which most will have become Schick-negative. Persons still remaining Schick-positive should be given a third series of inoculations, in spite of which a small number may still remain Schick-positive, apparently unable to produce antitoxin. There is reason to believe that the duration of the immunity so induced is permanent. Park has shown that 90 per cent have shown a permanent immunity over a period of nine years. It seems probable that the incidence of permanent immunity might in some measure be influenced by the occurrence of minor exposures to the disease. In those cases which again become Schick positive it is probable that they retain some degree of immunity in that they seem to retain an ability to form antitoxin rapidly when necessary. In these cases a very small stimulus will cause a rapid disappearance of the Schick test.

The greatest drawback to the use of this product for immunizing purposes is the fact that by using it one is sensitizing the individual to horse serum and thus increasing the hazards of any future emergency necessitating the use of horse serum. Park and several other men of wide experience feel that this factor is negligible but numerous reports indicate that this is indeed a factor that must be considered. The work of Gordon and Creswell is especially convincing, and it is hardly believable that any careful practitioner would willingly advise running this risk in such a wholesale manner when the uses of horse serum in present day medicine are becoming so rapidly increased. This must be thought of as a definite objection to the use of toxin-antitoxin for immunization to diphtheria, not great enough to preclude its use so long as no equally good substitute was available but enough so to stimulate search for such a substitute.

This was a factor in the prolonged delay in the usage of toxin-antitoxin in France. It probably was largely responsible for the development by Ramon of a vaccine which he called antitoxin that was rendered non-toxic by treatment with formaldehyde and heat. This treatment destroys the poisonous quality of the diphtheria toxin but leaves its immunizing properties intact. Ramon and many others have used it extensively in France and find it not only safe for injection, but also much superior to toxin-antitoxin in immunizing value. Since it contains no horse serum it has no sensitizing qualities. Quite a number of American investigators have also used it and substantiate all of the claims of Ramon and his co-workers. Ramon's method called for the subcutaneous injection of three doses; the first 0.5 c.c., the second 1 c.c. given three weeks later and the third 1 or 1.5 c.c. after another two weeks. Dick and Dick found a two week interval between all three injections very satisfactory. Rarely under the age of eight but with increasing frequency as age advances from this point, reactions of varying intensity occur with the use of toxoid. These reactions are principally local and usually unimportant from a general standpoint. They seem to depend upon a sensitization to some of the protein substances of bacterial or other origin contained within the injected fluid. They are not reactions to the diphtheria toxin. Thus they result from individual sensitivity to the same substances that are responsible for the pseudo-Schick reaction, and the Dicks maintain that if such a reaction occurs in the preliminary Schick test it is best to begin immunization with .1 to .25 c.c. of the toxoid. Results with toxoid yield from 95 to 100 per cent immunity after three injections as compared with from 75 to 80 per cent with toxin-antitoxin. Furthermore the time necessary for the production of immunity is much less, the Schick becoming negative usually in from five to six weeks.

In an effort to eliminate the sensitizing properties of toxin-antitoxin, Larson found that he could render diphtheria toxin innocuous without destroying its immunizing quality by mixing it with a solution of castor oil soap (sodium ricinoleate). He has had marked success in immunizing against diphtheria with this product. At the Gillette State Hospital for Crippled Children, where it has been used combined in the same solution with scarlet toxin for the past four years with an average daily population of 230 children, there have been six clinical cases of diphtheria with an additional 39 positive culture cases without clinical symptoms.

Twenty-five out of twenty-seven of these 39 that were so tested had virulent organisms in the cultures. Compared with the three year period preceding, when 252 positive culture cases occurred, most of them representing clinical diphtheria, this is most strikingly successful control.

It becomes evident when one considers the question that the development of the Schick test was the basic principle upon which all the recent advance in the understanding and control of diphtheria was based. The knowledge so attained was theoretically transferable to any contagious disease whose causative agent was known and in which the symptoms were produced through the agency of a soluble toxin. Thus it was that when the Dicks had demonstrated the organism of scarlet fever to be a form of hemolytic streptococcus liberating a soluble toxin which was responsible for the immediate symptoms of the disease, the path to rapid progress was clearly defined. The skin test for susceptibility, congenital immunity followed by increasing susceptibility with subsequent gradually acquired natural immunity as age advances, vaccination for the production of artificial immunity and finally antitoxin for the control of the disease were all suggested at the start.

In the use of the skin test considerable difficulty has been experienced by many observers. The Dicks defend the test very vigorously and say that while it is very exacting it affords results that are very reliable when all details as to procedure are carefully carried out. They claim 100 per cent reliability for a total of more than 35,000 persons. The method is similar to that used in the Schick test. One-tenth c.c. of a solution of toxin of such a titre that this amount represents the rather arbitrary unit of one skin test dose is injected into the skin of the forearm. In controlling artificial immunity the Dicks make another injection of twice this amount on the other arm. The test must be read under a strong light after from 18 to 24 hours. Any redness as large as 10 mm. in any diameter is regarded as positive. No induration is required and tests read after 24 hours are not reliable.

Using this test the Dicks have traced a curve of natural immunity essentially similar to that already described for diphtheria. As in this disease, the percentage of immunity in a given group is proportional to the opportunity for repeated subclinical exposure.

As to the artificial production of active immunity by vaccination the problem is somewhat different than in diphtheria. The streptococcus of scarlet fever produces its deleterious effects not only through the agency of a soluble toxin but also through actual invasion of the tissues, and many of the worst elements of the disease are a result of the latter quality. Present methods of study are not effective in measuring the antibacterial elements of immunity but are confined to the antitoxic factors. With even this handicap, however, the Dicks claim a tremendous success in artificial immunity, again 100 per cent efficiency. They inject subcutaneously graduated amounts of naked toxin at weekly intervals, increasing from 500 skin test doses in the first injection up to from 80,000 to 100,000 skin test doses in the fifth or last inoculation. If the Dick test two weeks later is still positive the fifth dose is repeated.

Others have found the reactions caused by the Dick technic too severe for general usage. The originators themselves admit that about 10 per cent of the injections are accompanied by general reactions, though how severe these are is omitted from the summary I am quoting. They do, however, state that no permanent harm has resulted from active immunization of 12,775 susceptible individuals.

The effort is constantly being made to find a method of immunization that is more practical than one requiring five injections and less severe in its immediate effects. Peters and Allison have used a method by which they spray the toxin into the nose, and have obtained rather a remarkable degree of success. No reaction whatever occurs during the immunizing process. Several workers have used scarlet toxoid successfully. Here also disagreeable reactions are lacking. The application of the toxin in ointment form to the skin represents another effort at simplifying the process of immunization.

In 1926 Larson began immunizing against scarlet fever with a toxin buffered, or rendered relatively non-toxic, by the addition of sodium ricinoleate. Certain advantages were noted in a toxin so protected over the naked toxin as used by the Dicks. Larger doses could be employed without bringing about disagreeable reactions and the degree of immunity produced seemed to be definitely greater than that produced with a like amount of toxin unbuffered. Later this toxin was mixed with a suspension of the organisms of scarlet fever, thus using not only a toxin but also the organism for immunity production. The Dicks have viciously attacked this method of immunization as totally incompetent and misrepresented, giving a wholly false sense of security because of its total failure to accomplish its ends.

Since November 1, 1926, the Board of Health of the City of Minneapolis has been using this vaccine, combined with diphtheria toxin in the same dose. From that date until August 31, 1929, a total of 24,212 injections had been made. A complete course of treatment, three doses, had been given to 6,953 children and incomplete courses, one or two doses, to 2,205 more, making a total of 9,158 children immunized or partially so. It was estimated that 4,000 more were treated by this method by private physicians. The total number of children in Minneapolis between the ages of one and sixteen was estimated at 105,000. During the observation period 3,973 cases of scarlet fever were reported. Of this number only 55 were in children who had received the ricinoleated vaccine. Scarlet fever was thus ten times as common among those children who had not received Larson's vaccine as among those who had. Parks claims for toxin-antitoxin only a reduction to one-fifth the incidence in those who have not received such vaccination against diphtheria. From this experiment it would seem that practically the ricinoleated scarlet fever toxin is very efficient in controlling scarlet fever.

Again, at the Gillette State Hospital for Crippled Children, where this vaccine has also been used in combination with the diphtheria toxin, from May, 1926, to July, 1930, only eleven cases of scarlet fever occurred. Of these eleven, five occurred within a week after admission to the hospital. Thus only six cases of scarlet fever developed in patients that had been in the hospital long enough to be immunized. During this time twelve adult attendants who had not been immunized developed the disease. Any of the attendants or of the eleven patients would have been capable of starting an epidemic if the number of susceptibles had not been very low. During this period 75 per cent of the population came from rural communities.

The duration of artificially produced immunity is a question that can not as yet be settled. The Dicks claim that retests made at the end of one, two and three years indicate that 90 per cent of patients who are immunized to the point of entirely negative skin reactions, retain their immunity. Between 5 and 9 per cent require second immunization. It seems fair speculation that the duration of such immunity might in some measure at least be influenced by the occurrence of slight subclinical infections and that thus the conditions of living, such as crowding, etc., might play the same role here as they do in the development of natural immunity.

The same factors that complicate the problem of artificial immunization render the problem of antitoxin more difficult. For maximum efficiency a serum that is both antitoxic and antibacterial should be produced. This has led to two principal methods in the production of scarlet fever serum. The first is made by injecting the horse with toxin alone, thus stimulating the production of a pure antitoxin. In the second method an attempt is made to produce an antibacterial serum as well by inoculating live organisms into an agar plant that has been placed within the body of the animal. Thus not only is the horse forced to produce an antitoxin but also reactionary bodies against the bacteria themselves. No marked superiority has as yet been demonstrated for either method, though at present most commercial serums are produced in the latter manner.

There is little doubt but that scarlet fever antitoxin is effective in controlling the immediate symptoms of the disease. Here, as in diphtheria, it should be given early for maximum effect. There is much more generally expressed doubt as to the value of the serum in preventing complications. The latter, it will be noted, are usually a result of bacterial invasion and not of purely toxic origin. On the other hand certain enthusiastic supporters of the serum treatment insist that the complications are very materially reduced by the use of serum. Still other writers hold that the serum does not affect the incidence of complications in mildly toxic cases, but that it does in the severe types. Thus two general opinions are to be found among writers on the subject: one that the serum should be used as soon as scarlet fever can be diagnosed, regardless of severity, or even as soon as scarlet fever is suspected (Dick); and the other that would limit its use to those cases that show marked toxemia at the start. The latter opinion is certainly the more conservative and it seems to me that conservatism has virtue in this time of wholesale serum injection. Mild scarlet fever is not a severe disease. Even moderate grades of serum disease are much more discomforting, and serum reactions are particularly common following the administration of scarlet fever serum. It is true that serious complications may supervene even following the mildest cases of scarlet fever, but until it is thoroughly proven that the serum is of considerable benefit in preventing such accidents in the mild cases, we are not justified in subjecting the patient to the hazards and discomforts that so frequently follow its use. There can, however, be no doubt that it should be used in the moderately severe and severe cases. The use of scarlet fever serum for prophylaxis in case of exposure is mentioned only to be condemned. It should never be used then. Before the discovery of antitoxin, convalescent serum was used in the treatment of scarlet fever with some degree of success. The obvious difficulties encountered in procuring it when needed greatly limited its use in general practice.

When scarlet fever antitoxin first appeared, it was thought that it would be useful as a means of demonstrating the skin blanching phenomenon (Schultz-Charlton test) and thus aid in clearing the diagnosis in certain doubtful skin eruptions. Toomey and his co-workers have shown that most of the serums are useless for this purpose, some even giving rise to an increased redness at the site of injection. These authors aptly suggest that if the blanching test is dependent upon the antitoxin content of convalescent serum, then most of the commercial serums are devoid of antitoxin.

It is usually a safe maxim that nothing is acquired without a price being paid for it. This is true of the progress that is being made against the two diseases under discussion. New problems arise, by-products of the new methods employed, which while less of a menace than the original difficulty must nevertheless be dealt with. Two problems which pertain especially here are that of the carrier and that of sensitization to horse serum. The first of these has been recognized as a formidable obstacle in the control of diphtheria for many years. It bids fair to become a much greater problem as the number of immunes increases. This is especially true in institutions where it is possible for a large number of inmates to become carriers after immunization in such an insidious manner as to produce no symptoms whatsoever. Only the closest imaginable control, combined with frequent cultures, will cope at all with this menace. While the carrier has long been recognized as a menace as regards scarlet fever, the lack of method for identification has limited the problem to one of surmise. The precise methods—culture, etc.—which are bound to develop from the increasing knowledge of this disease, give promise of duplicating for scarlet fever what is happening in the case of diphtheria. Much must yet be done in the control of these diseases along the line of prevention and cure of the carrier.

Even more important is the problem of sensitization to horse serum. While some of those who deal with this factor in the immunization of thousands of cases are inclined to think lightly of it, the physician who encounters the single case of sensitization is apt to regard this phase of the subject more seriously. He realizes that a single death or near death from the giving of a serum, were it traced to methods employed in the efforts to prevent disease, would do more damage to the cause of prophylaxis than a dozen deaths from the lack of it could rectify. Such is the psychology of the uninformed. With the present trend in medical practice it will not be long until a great majority of individuals will not only have become sensitized to horse serum, but will have received one or more shock doses before they have run the gamut of common diseases with their prophylactic and curative procedures. Certain observations seem to indicate that the severity of the reactions increases with the number of injections. While this phase of the subject should not be overemphasized, at the same time it is not wise to totally disregard it. A sensitized state may hinder or delay the giving of therapeutic serum in circumstances where this delay is costly, and until we understand more about the subject of protein sensitization, or anaphylaxis, and are better able to cope with it, we will be wise if we avoid any unnecessary contact with it.

Regardless of what policy we adopt, we probably shall always have with us the sensitized individual to whom it is absolutely necessary to give horse serum in some form. Such individuals may be naturally sensitive (the more dangerous type) or they may have been sensitized through a previous injection of horse serum. Therefore, before serum is given, careful inquiry should always be made as to whether or not any form of serum had ever before been given. If not, it is wise to inquire as to the occurrence of asthma, especially horse asthma, hay fever, eczema, urticaria or other manifestations of allergy in either the patient or his near relatives. Positive answers to either question obligate the physician to determine whether the patient is sensitized. Even though no such history is obtained, it would still be the more conservative procedure to test the patient for sensitization before introducing a large amount of serum.

This is especially true when the injection has to be made either intravenously, intraperitoneally or intraspinally.

Mackenzie and Hanger have covered this subject in magnificent detail and their ideas on technic are as follows: To determine sensitivity, a minute amount, not more than 0.05 c.c., of a 1 to 10 dilution of serum is injected into the skin of the forearm. They advise the injection of a like amount of human serum or normal saline at the same time as a control. If the wheal induced by the injection enlarges and becomes surrounded by a zone of erythema in from ten to twenty minutes the patient is sensitive, provided the control does not behave the same way. In extremely sensitive individuals an enormous reaction may be induced. Pseudopod-like projections at the edges of the wheal occur with the higher degrees of sensitization. They advise the dilution of the serum because in this way false reactions do not occur. One can not depend altogether upon the character of the skin reaction as an indication of the degree of sensitivity of the individual. Severe reactions are not unknown, they say, in the absence of a positive cutaneous test. Therefore, even though the test may be negative, it is wise to proceed cautiously whenever a suspicious history of sensitization is obtained.

In the sensitized person desensitization is necessary. These authors recommend the initial injection of .01 c.c. of serum suspended in saline and given subcutaneously. Every half hour this injection may be repeated, doubling the dose of serum each time unless toxic symptoms occur. In such case, the next dose should be of the same amount as the preceding in order not to proceed too rapidly. When as much as 1.0 c.c. of serum has been tolerated at one time subcutaneously the next dose may be given intravenously if this method of injection be necessary. This should be reduced to .1 c.c. in saline and may be doubled each twenty minutes thereafter until the full therapeutic dose has been injected.

In cases where intraspinous injection is to be given, one should continue with the intravenous injections until 10 c.c. are tolerated. Then, after the proper interval, a like amount may be cautiously injected into the spinal canal.

Occasionally individuals are encountered in whom it seems to be impossible to bring about sufficient desensitization. Still others may be desensitized more rapidly than this technic prescribes if no reactions occur after the early doses. Almost all individuals, however, can be desensitized to the point where serum in therapeutic dosage can be safely given.

CEREBROSPINAL MENINGITIS*

Carl O. Kohlbry, M.D.
Duluth

Cerebrospinal, epidemic, or meningococcic meningitis, a disease constantly present in all large communities and often epidemic in character, continues to present difficulties in control despite our knowledge concerning it. The purpose of this paper is to summarize recent work on this subject.

Cerebrospinal meningitis is essentially a disease of children, though it may occur at any age. In Neal's series of cases in New York City, 70 per cent occurred during the first ten years of life. A great many cases appear during the first year of life and at this age it is the most common type of meningitis.

Nearly all epidemics occur during the winter and spring months; overcrowding is a factor in spreading the disease. Apparently it is a disease to which most persons have a natural immunity; multiple cases in a family are uncommon. Leukowicz states that the meningococcus is really a very slightly pathogenic organism, but its feeble virulence is largely counterbalanced by its remarkable power of multiplying, which enables it to appear at times in blood films or to provoke extensive skin rashes in septicemic cases. As soon as the body develops some general immunity, the meningococci in the circulation are impaired in vitality and soon are completely destroyed. However, a marked difference in virulence in various epidemics occurs.

DISSEMINATION

Meningitis is disseminated through the medium of healthy carriers. The meningococcus is found at some stage in the nose and throat of those ill with the disease in over 90 per cent of cases. It usually disappears in from five to fourteen days. Mathers and Herrold found that among 140 immediate contacts (tent-mates) of cases of meningitis, 27 per cent were carriers. Seven of these were persistent carriers. Of 15,257 men, members of organizations in which meningitis had occurred, 44 per cent yielded positive meningococcic cultures. They found two types of carriers: temporary and persistent. The persistent carriers, individuals yielding positive naso-pharyngeal cultures over a long period of time, were few in number and only rarely developed meningitis. In the cultures from these carriers the organisms were present in predominating numbers. The temporary carriers were more numerous, but their cultures showed few meningococci, which persisted only over a short period. The biologic type of meningococcus predominant in the camp epidemic at the time was identical with that among the chronic carriers; also the type found in the cases and in the immediate contacts was the same. These facts suggest that there is a close relation between cases of epidemic meningitis and carriers. They feel that the persistent or chronic carrier is especially dangerous. Gates reports that specific agglutinins have been found in the blood serum of chronic carriers, evidence that their relative immunity may be due to these antibodies.

MORTALITY RATE

The general mortality rate from this disease has been reduced from approximately 70 per cent before the introduction of serum to variously estimated figures of 23 to 35 per cent, since. These figures include cases in infants under one year of age. This high death rate may be due to several factors: (1) An extremely virulent organism causing a fulminating meningitis; (2) an organism of different type than those used in producing the serum; (3) late recognition of the disease. The last mentioned is certainly the most common. Meningitis occurring in infancy, however, is still carrying a decidedly higher mortality rate, approximately 45 to 50 per cent. The causes for this higher mortality are late recognition of the disease, and lack of resistance to the organism.

Gates has injected volunteers with a meningococcic vaccine and later demonstrated specific meningococcic agglutinins in their blood serum. I have come across no other reference regarding active immunization against the disease.

SYMPTOMATOLOGY

As to the disease itself there are four types:

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, Minn., July 14, 1930.

(1) The common type, usually seen in older children or adults; (2) the fulminating type; (3) the infantile type, and (4) the septicemic type. It may run an acute course, the patient either dying or recovering after the use of serum; it may be greatly prolonged so that many doses of serum need be given before recovery or death ensues; it may relapse after apparent recovery, indicating perhaps some walled off focus of infection; and there is a class in which blocking occurs at the base of the brain which is very apt to be fatal.

The symptoms of the average case are familiar to all. The onset is acute, frequently with a chill. There are fever and headache. The patient is irritable, restless, and vomits. Shortly, the typical signs of meningitis develop, notably hypersensitiveness, delirium, stupor, convulsions, rigidity of the neck, increased reflexes, irregularities of respiration, Kernig and Brudzinski signs.

The fulminating type is the most malignant form. It runs a very acute course and usually kills within a few hours to a day. The picture is that of a violent general sepsis that utterly overwhelms the patient. If these fulminating cases can be tided over the first forty-eight hours they may respond to treatment.

The infantile type is easily overlooked in its early stages, starting usually as an obscure fever with gastro-intestinal symptoms, followed by convulsions, strabismus, and bulging of the fontanel. The bulging fontanel is the most important finding.

The septicemic type has only recently been recognized. All fulminating cases with purpuric rashes are probably of this character. In addition there is another group with a prolonged febrile state, frequently arthritic symptoms, and a mild roseolar or petechial eruption, much resembling typhoid fever. These patients may develop meningeal findings later, though some never do and eventually recover.

The usual type of meningitis may become chronic. The symptoms of this condition are continued irregular temperature, decided emaciation, vomiting, hydrocephalic cry and convulsions. The cause of this picture is frequently a posterior basic meningitis with a collection of plastic exudate at the base sealing up the foramina and giving rise to a hydrocephalus.

Relapses occur at times, probably in 5 to 10 per cent of cases. Many of these are due to the fact that the patient is not entirely well at the time of his supposed recovery and the process flares up. Under active treatment they often clear up. The patient should not be discharged till the spinal fluid is normal and its culture negative.

Conjunctivitis accompanies the disease very frequently; the discharge may show meningococci. Herpes when present also may show the organism in smear. Irido-choroiditis, usually purulent, occurs at times.

Deafness is one of the common sequelæ. Hydrocephalus occasionally follows. Mental deficiency results much less often than would be expected.

THE ORGANISM

The causative organism of cerebro-spinal meningitis is the meningococcus, often spoken of as the diplococcus intracellularis of Weichselbaum. This organism is a quite typical gram-negative diplococcus. It is practically always found at some stage of the disease in the spinal fluid, and often in blood cultures. In the fluid it may be intra- or extracellular, the relation to the leukocytes depending to great extent upon the intensity of the disease and the response to treatment. In severe cases there are many organisms, mostly extracellular. In favorably responding or milder cases they are fewer and mainly intracellular. Culture of the fluid usually shows a growth in eighteen to twenty-four hours. The organisms are more likely to be found in the last portion of the fluid withdrawn. The results of a Gram stain are not always reliable. A definite diagnosis must never be made on the result of a stained smear; it must rest on the results of a culture.

Meningococci fall into two large biologic groups, the typical meningococcus (Group I) and the parameningococcus (Group II). A great variety of intermediate strains related to one or the other of the two large groups occur, however, and Gordon has classified these intermediates into two groups which he calls groups three and four. The biologic differences are of great importance, particularly in the identification of the organism and the produuction of a potent serum. The meningococci of groups one and two are responsible for seventy-five to eighty per cent of all cases of meningitis.

It is generally believed that the toxic substances derived from the meningococcus appear as a result of massive cell autolysis (endotoxin) though highly toxic filtrates may be obtained from cultures in which there has been comparatively little cell autolysis. Schwartzman has succeeded in producing skin reactions with filtrates of meningococcus cultures and in being able to neutralize them in a high percentage of cases with antimeningococcic serum.

The fluid withdrawn at the first puncture most often yields the organism. However, I have seen organisms appear *only after* the giving of the serum. The best culture medium for its growth is probably the dextrose semisolid agar as prepared by Gosling. In 89 consecutive meningococcic cases tested by her, growth was obtained in eighty-one; at times growth occurs in this medium only; frequently growth occurs here when a smear is negative for organisms. Growth occurs in from eighteen to ninety-six hours. The identity may be proven by agglutination and fermentative tests.

PATHOLOGY

The nose and throat are the portals of entry of the organism into the body. Meningitis is first a case of naso-pharyngitis. Invasion from the nose and throat may occur in two ways: (1) By direct infection from the nose through the lymphatics; (2) by a primary invasion of the bloodstream causing a meningococcus septicemia with secondary localization in the meninges. Most authorities now favor the latter course.

It is probable that there is a brief invasion of the meningococcus in the blood in practically all cases of meningitis. Herrick found positive blood cultures in 45 per cent of his cases. Other authors give the incidence as 25 per cent. The duration of the blood infection before the development of meningitis may be extremely short; the two may appear coincident, as in the fulminant cases; or it may be of days' duration. It is possible to have a septicemia without infection of the meninges. This is usually transient, perhaps not over a few hours, but on the other hand it may last for days or even months, at times to be followed by an acute meningeal invasion. Some cases never pass beyond the septicemic stage. Richmond reports twenty-one cases of which seven remained septicemic only. Even fulminating cases ending fatally may show no evidence of meningitis at necropsy. Septicemic cases are less frequently seen in children.

Before the entry of the organism into the cerebrospinal fluid is described it will be wise to describe the circulation of the fluid. The fluid is secreted principally by the choroidal plexuses in the lateral ventricles. It flows through the foramina of Monro from the lateral ventricles into the third ventricle, through the aqueduct of Sylvius into the fourth ventricle, and from here gains access to the cisterna magna and the basilar system of cisterns by way of the foramina of Luschka and Magendie. The cisterna magna may be regarded as the distributing center of the fluid, as from here it gains access to the other cisterns and to the cerebral and spinal subarachnoid spaces.

Absorption of the cerebrospinal fluid occurs through the arachnoid villi into the cerebral sinuses or into the veins of the meninges.

Present opinion points to the entrance of the organism into the central nervous system via the blood stream through the choroidal plexuses. To do this the usually efficient barrier of the plexus must break down. Many observers contend that the cortex is also involved primarily, along with the lining of the ventricles. Leukowicz believes we must consider meningitis as a primary ventriculitis (choroido-ependymitis) while the lesions of the meninges constitute only a secondary phenomenon. He believes that no autonomous meningitis can exist independently of the ventricular infection nor require a serum treatment on its own account. Rolleston and Dopter agree with this in part. The barrier of the choroid plexus is overcome through inflammation of the plexus itself, much as in the metastatic skin lesions before mentioned, weakening the epithelial lining of the plexus villi and allowing the organisms to pass through.

If the consistency of the brain is soft and flaccid, as exists in infants, the cerebral edema and condition of pressure soon results in an obliteration of the sulci of the cerebral convexity. In those parts of the subarachnoid spaces that have thus lost their connection with the ventricles the inflammatory processes disappear quickly, according to Leukowicz. If large purulent layers are already present in the sulci the pus disintegrates, young connective tissue grows in and forms sclerotic plaques. The sulci of the convexity being closed, removing the largest area of fluid absorption, the cisternæ of the base remain the only part of the subarachnoid space within the cranium communicating with the ventricles. Consequently these alone remain filled with pus. This type of block explains the pathogenesis of the posterior basic type of meningitis as seen in infants and its resultant hydrocephalus. Adhesions obliterating the basilar foramina can also bring about this picture.

With the progress of age, however, the consistency of the brain becomes more firm and resistant, and changes of configuration leading to obliteration of the sulci can develop only after long duration. The subarachnoid spaces of the convexity thus remaining passable for a long time, are the site of an active resorption of the fluid and also of an abundant accumulation of its cellular elements. As the drainage of the ventricles is sufficient, hydrocephalus does not soon develop. On the other hand, the brain, not being able to markedly change its configuration, suffers from the pressure exercised on it by the osseous cranial walls and manifests this by violent cerebral symptoms.

Another spinal type of block may occur, due to an edema of the cord. This spinal type is more common in infants and is related to the increased size of the cord in proportion to the size of the spinal canal at this age. Occasionally a condition of "dry canal" may simulate spinal or basilar block and must be differentiated from them.

DIAGNOSIS

The diagnosis of cerebrospinal meningitis rests upon the finding of the meningococcus in the spinal fluid. The fluid when taken early in the septicemic invasion stage may be perfectly clear and normal microscopically. However, several hours later, turbidity may be manifest. The usual meningococcic fluid is frankly turbid. As a rule there is a decidedly increased cell count running into hundreds or thousands per cubic millimeter. The cells are usually polymorphonuclear in type, though occasionally lymphocytes predominate. Lymphocytes are apt to predominate in the very early fluids. There is an increased amount of protein and a decreased amount of sugar present. The gram-negative diplococci are almost always to be found in varying numbers on smear, and grow fairly readily in suitable culture media.

The white blood count is of varying significance. There is practically always at least a moderate leukocytosis. In some epidemics, however, it is greatly increased, with a high percentage of polymorphonuclears. Richmond reports counts from twenty thousand to fifty thousand with 90 per cent polymorphonuclears. It is safe to state that in an unexplained fever with a white blood count of over twenty thousand, meningitis should be suspected.

The meningococcus may be found in blood culture. Special media such as ascitic broth, blood broth, or blood agar, should be used, as the organisms grow poorly in ordinary media. Blood cultures may be very important in the recognition and treatment of meningococcic sepsis.

THE SERUM

Before treatment is discussed a few words about antimeningococcic serum are in order. The serum is produced by the injection of horses with living or dead cultures of the meningococcus over a period of time, and systematic bleeding thereafter. All serums are supposedly polyvalent for the four different strains of the Gordon classification as specified by the Government. The serum of some laboratories contains antibodies for additional strains. The problem of determining the best method of preparing a serum of value against all strains of the meningococcus still is incompletely solved. It is possible that a serum prepared with the use of only the four Gordon strains may be more potent than one prepared with a greater number. It has been shown that the concentrations of the different types of antibodies varies with the period after injection that the horses are bled. The value of therapeutic serums may be tested by the use of several immunity reactions, of which the agglutination test seems to be the best. It, however, is not a consistently accurate measure of the serum's real therapeutic value.

The serum when prepared contains agglutinins, complement-binding antibodies, bacteriotropins or opsonins, and anti-endotoxins. Its effect is to injure the meningococcus, reduce it in numbers, alter its size and staining properties and render it more readily taken up by the leukocytes (phagocytosis). The disintegration products of the organisms are also neutralized by the anti-endotoxins of the serum.

TREATMENT

The symptom-complex of antimeningitis consists of symptoms of sepsis from the purulent inflammation, symptoms of meningeal irritation, and pressure symptoms from the collection of exudate in the ventricles and subarachnoid space. In treatment, sepsis must be combated by serum injection into the meninges, and the equally important hydrocephalic pressure symptoms relieved by withdrawal of spinal fluid. It may be accepted as a general rule that unless the serum is introduced directly into the meninges the course of the local conditions will be little affected. When blood stream infection is present, or presumably so, subcutaneous or intravenous serum is also to be used.

Treatment may be divided into two parts: (1) treatment with serum; (2) general management.

If we grant that the original site and "feeder" of the infection is in the ventricles, the logical aim is to provide a sufficiently intense serum reaction in the ventricles and to maintain it for several days till disappearance of the meningococci occurs. This does not mean that serum necessarily must always be given directly into the ventricle itself. Serum injected intraspinally by the lumbar route penetrates into the ventricles in quite a sufficient concentration in almost 80 per cent of cases. The concentration of serum in the ventricles shortly after lumbar injection is often as high as 10 per cent and even after twenty-four hours may still be from 1 to 3 per cent. Serum injected into the general circulation is secreted into the spinal fluid only in small quantities and very slowly so that its action in the central nervous system cannot be depended upon. All cerebrospinal meningitis, therefore, demands intraspinal treatment. When meningitis is suspected, lumbar puncture should be done at once. The old dictum "a cloudy fluid demands antimeningococcic serum until *definitely proven* other than meningococcic meningitis" still holds true. Failure to observe this rule is often costly, as treatment with serum is most likely to give results when given early in the disease, the earlier the better. No harm, other than obscuring the picture for a time, results from the giving of serum, if proper precautions are taken. Meningococci occasionally are not found in cloudy fluids for several days, during which precious time is lost. The mere giving of serum may serve to bring the organisms forth. Serum should be continued until the organism found is proven beyond question not to be the meningococcus.

Specific bacterial immune bodies, agglutinins, opsonins, and antibacterial substances are usually absent, or present only in very small quantities, in the cerebrospinal fluid in meningococcic meningitis. Immune substances of similar type have been demonstrated in the blood of meningitis patients, however.

When spinal puncture is performed enough fluid should be withdrawn to exceed by five cubic centimeters or more the amount of serum it is desired to give. This is a safe working rule. The serum given should be allowed to run in slowly by the gravity method. Neal has at times given more serum than the amount of fluid withdrawn when it has run in easily by the gravity method, carefully observing the patient during the procedure. This is not to be recommended to the average practitioner.

The amount of serum to be given at each intraspinal injection depends upon the age of the patient. Young infants may be given 10 to 20 c.c.; adults up to 60 c.c. The interval between the injections has varied in different hands from eight to twenty-four hours. As serum injected intraspinally does not entirely pass out of the subarachnoid space for twenty-four hours, a twenty-four hour interval seems logical. Neal has thought it probable that removing fluid at more frequent intervals might remove cells that had been stimulated to a high degree of phagocytic power and were therefore actively combating the infection. Since the serum has so little bactericidal power itself, the administration of large amounts at frequent intervals seems unnecessary to her, besides subjecting the patient to considerable added pain and discomfort. Sophian advises a twenty-four hour interval. However, when the increase of pressure is great, lumbar puncture for its relief may be done at more frequent intervals and serum given. In Neal's hands the twenty-four hour interval of injection has yielded a mortality of 23 per cent in a large series of patients, a mortality rate lower than the average.

The average case requires from four to eight injections although at times a good many more are necessary. There are two main guides to the continuation of treatment: (1) the findings in the fluid at each puncture; (2) the clinical condition of the patient. While the fluid has a tendency to become clearer macroscopically as the disease improves, it may remain quite turbid due to the excitation of leukocytosis by the serum itself. As the patient responds, the organisms in the fluid become less numerous and more frequently intracellular, frequently appearing clumped together and failing to grow in culture. Such findings in conjunction with clinical improvement of the patient are indications for cutting down on the frequency of injections to 36 to 48 hours. Serum treatment should be continued until spinal fluid smears are negative for bacteria and cultures from it show no growth, always being prepared to institute treatment again if the patient's condition becomes worse or the fluid findings retrogress. The spinal fluid cell count is not an accurate guide to the discontinuance of serum. It is frequently necessary to do one or more spinal punctures after serum is discontinued for the relief of pressure symptoms.

Reaction of spinal fluid injection.—The injection of serum is usually accompanied by pain referred to any or all of the region affected. It usually subsides by the end of the operation, though it may continue for several hours. Usually there is a drop in blood pressure, at times quite marked. Fluid may be withdrawn till the pressure is normal, which roughly corresponds to ten to twenty drops per minute. Shock occurring during or after injection is usually due to the injection of too large a quantity of serum, too rapid injection, or undue pressure excited during its injection, and at times calls for the immediate withdrawal of serum and fluid when possible. Adrenalin and atropin may be used.

Intravenous serum. — The general opinion seems to be that intravenous serum should be given only to those cases with evident sepsis as manifested by joint signs, rash, or positive blood cultures, or in the very early cases when the patient is presumably in the septic stage. It may also be given when no improvement occurs after thorough spinal and cisternal treatment. Herrick advised 80 to 150 c.c. per dose; other authors use 20 to 50 c.c. The dose may be repeated at twenty-four hour intervals for several days until improvement occurs. It must be remembered that intravenous serum is prone to elicit severe and even fatal reactions; this fact has led several authors to discontinue its use. Attempt at desensitization should always precede its administration. Serum may be given by the subcutaneous or intramuscular route with greater safety.

Cisternal treatment.—When there is clear indication of block, puncture of the cisterna magna and serum injection at this site is often of the greatest aid. It also may be used when treatment via the lumbar route is not giving results. I am not going to attempt to describe its technic; suffice it to say that it is not overly difficult. Its advantage lies in the fact that serum reaches the strategic points more surely than by the lumbar route. As a rule cisternal treatments are well tolerated by patients. The dangers of cisternal treatment are intracranial compression, a jamming herniation by release of pressure, hemorrhage over the medulla from trauma to the spinal veins, and trauma to the medulla or cerebellum from improper puncture. Such occurrences are rare with correct technic. It is well to remember that patients who show evidence of anaphylaxis do not respond well to intracisternal serum, possibly as a result of an edema of the brain.

Ventricular treatment.—Some feel that the ventricular injection of serum is superior to the cisternal injection, believing it less dangerous and even more efficacious. Particularly is this felt in the case of infants, where its performance is usually a rather simple matter. Use of the cisternal or ventricular routes, when indicated, should result in further lowering of the mortality.

Combined treatment.—Some authors routinely treat cases by a combination of lumbar and cisternal or ventricular injections with good results.

General care.—The general care of the patient must not be lost sight of. Sedatives are necessary for restlessness, elimination must be secured, the fluid and food requirements met. If necessary, tube feeding should be used. Saline subcutaneously may be administered. At times blood transfusion is valuable.

The patient should not be discharged until the spinal fluid and cultures are normal and he has been temperature-free for at least one week.

Other types of treatment.—The treatment of meningococcic sepsis without meningitis is intravenous serum. Richmond treats these cases by intraspinal injection as well and feels that it sometimes prevents meningeal infection.

Neal, Banzhaf, and their co-workers have used an antibody preparation made by concentrating the serum, partially purifying its antibodies by precipitation, and then redissolving in sodium chloride. The agglutinating power of this antibody preparation is much higher than the serum from which it is made. It is given intraspinally in doses of 20 c.c. every twenty-four hours. With such a satisfactory preparation their mortality in twenty-four cases was 12.5 per cent. Neal tells me in a personal communication that this procedure is still in an experimental stage.

An autogenous vaccine has been used in chronic cases both subcutaneously and intraspinally, with good results at times. The use of convalescent serum is barely mentioned in the recent literature and the value of this treatment I do not know.

PROGNOSIS

The earlier the diagnosis and institution of treatment, the better the prognosis. The spinal fluid sugar findings offer distinct prognostic aid. The normal fluid sugar content is forty-five to sixty-five milligrams per hundred cubic centimeters. Before treatment is instituted it drops as a rule to about twenty milligrams but with improvement it gradually rises until it becomes normal again about the ninth day. Both the fermentative action of the meningococcus and the glycolytic action of the polymorphonuclear leukocytes have been considered the etiological factors in the decrease of the spinal fluid sugar. In the fatal cases it remains low. In infants it is often as low as thirteen milligrams and increases much more slowly, not reaching normal during treatment. Caffey and his co-workers believe the slow return to normal in infants is due to the slower subsidence of the inflammatory cellular reaction which they exhibit.

Estimation of the spinal fluid chlorides does not give valuable prognostic information.

Change of serum.—When the patient does not show the expected improvement in spite of thorough treatment it is often wise to use a different serum. It has several times been shown that some brands of serum will not control certain epidemics. The agglutination test as a measure of a serum's effectiveness is not certain; one must depend on the therapeutic response in determining the value of the serum used.

Serum sickness occurs in about 70 per cent of all cases, usually from the fourth to the fifteenth day.

DIFFUSE SUBCORTICAL SCLEROSIS OF THE BRAIN*

J. Charnley McKinley, M.D., Ph.D.
Minneapolis

THE confusion of classification and terminology which surrounds the concept of diffuse cerebral sclerosis and the lack of sufficient fundamental data with which to clarify our concepts justifies the reporting of further individual cases of the condition. During the time in which the number of reported cases is small, the publication of additional cases will likely increase this confusion; but at least it will tend to break down insufficiently grounded nosological hypotheses, though it may leave little in the way of satisfactory understanding in their place. Nevertheless, we shall probably eventually acquire through such reports a sufficiently large series of cases so that the more obvious features of the disease can be seen with reasonable perspective, whereupon our terminology can be constructed with sufficient logical basis, such that some general acceptance of terms may be attained.

Coinage of names for the condition and its types has been indulged in by various writers to such a point that one becomes quickly disoriented in the maze of words one might be expected to keep in orderly array for the condition and its variants. For example, the following terms have all been proposed as the most suitable for one or another phase of the condition or for the condition itself:

1. *Encephalitis periaxialis diffusa* or Schilder's disease. The term was introduced by Schilder[1] in 1912 to designate a type of diffuse cerebral sclerosis involving the white matter of the hemispheres in childhood and separated from the diffuse gliomas of the brain. He assumed a toxic etiology which justified the implication of brain inflammation in his terminology. Bielschowsky[2] limits the term to such cases of cerebral sclerosis as show strong evidences clinically or pathologically of an inflammatory process. He presents such a case. Other writers (for instance Bouman[3] and Collier and Greenfield[4] and several Americans) have applied the term to cases which they considered primary degenerative. Ferraro[5] presents his cases as the "familial form of encephalitis periaxialis diffusa"; thus hereditary forms have also been classified under Schilder's terminology.

2. *Progressive degenerative subcortical encephalopathy.* This term was suggested by Globus and Strauss[6] to supplant Schilder's term of encephalitis periaxialis diffusa. Globus and Strauss obviously considered the condition as primary degenerative.

3. *Symmetrical centro-lobar cerebral sclerosis* (La sclérose cérébrale centro-lobaire a tendance symétrique) is the term used by Foix and Marie[7] to mean a chronic form of encephalitis periaxialis diffusa of Schilder, or a form which may come to spontaneous arrest.

4. The term *aplasia axialis extracorticalis congenita* (Pelizaeus-Merzbacher disease) is properly applied, according to Liebers,[8] only to cases occurring in a single family which has been reported through four generations by Pelizaeus, Merzbacher, Spielmeyer and Liebers. The condition occurred in fourteen members of the family and in each case ran a chronic course after an onset in infancy.

5. Krabbe[9] described a *familial infantile form of diffuse brain sclerosis* with an acute course.

6. For the hereditary forms in general of primary degenerative diffuse sclerosis involving the subcortical white matter, Bielschowsky and Henneberg[10] have introduced the designation *leucodystrophia cerebri progressiva hereditaria.*

It is hoped that the present report will not add to the confusion.

PRESENTATION OF A CASE

A white boy, aged 2.5 years, was admitted to the Pediatrics Service of the University Hospital November 11, 1929. His birth was normal. He weighed eight pounds at birth. He was breast fed for nine months. Child was perfectly well until July, 1929, at which time he weighed twenty-six pounds. Since that time the weight has been stationary. Sat up at 8 to 9 months; walked at 1.5 years; had his first tooth at 17 months; had sixteen teeth at the time of admission. He began talking at one year but has never talked very much. Since the onset in July, 1929, the patient has ceased speaking altogether. It was noticed by the parents that the baby fell down frequently without stumbling; later was entirely unable to maintain his balance. Shortly thereafter he became unable to walk at all, and in August he could not crawl. At that time stiffness of both legs was noticed, and a short time later he could sit only with difficulty, being obliged to double his legs under him (squatting) to maintain his trunk in the erect position. Since early in October he has been unable to use his hands and arms. Both extremities are kept extended and no voluntary movements are made. The head has been held in opisthotonos for some weeks.

---

*From the Division of Nervous and Mental Diseases, University of Minnesota Medical School, Minneapolis. Presented before the Minnesota Academy of Medicine, October 8, 1930.

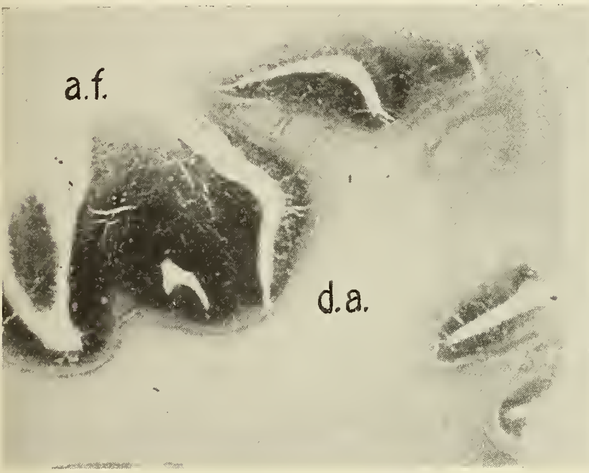

Fig. 1. Left frontal area of brain. a.f.—arcuate fibers. d.a.—degenerated area, the subcortical white matter. Weigert's myelin sheath stain. X 2.

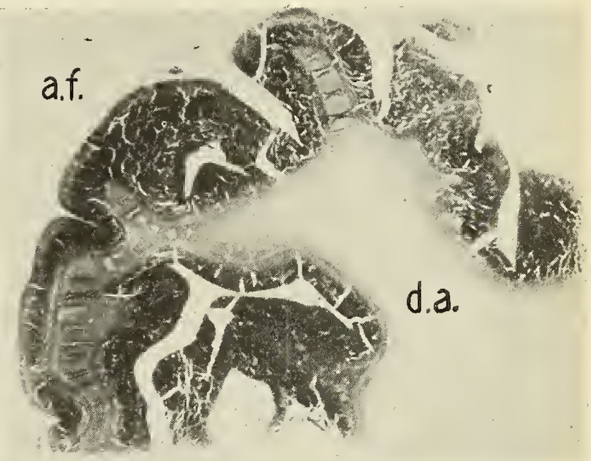

Fig. 2. Left parietal area. a.f.—arcuate fibers. d.a.—degenerated area, the subcortical white matter. Weigert's myelin sheath stain. X 2.

There was no previous illness. Father and mother are both living and well. They are cousins. The mother had an operation for goiter. The patient is the second child.

A brother lived to the age of 2 years 9 months and became ill much like the patient, developing speechlessness. He was never able to walk and became spastic in all extremities before death and died finally of bronchopneumonia.

Examination.—Physical examination by the pediatricians showed fair development but slight emaciation. The pupils were fixed to light and dilated. The eyegrounds were negative. Throat and mouth showed no pathology. Heart, lungs and abdomen were normal. All the extremities showed atrophy of the muscles. The reflexes were increased in the upper extremities. Reflexes could not be obtained in the lower extremities because of spasticity. Both lower extremities were very spastic and held in constant extension.

Laboratory findings.—Blood examination showed hemoglobin 91 per cent, red blood cells 4,910,000, white blood cells 11,000, polymorphonuclears 40, lymphocytes 58, monocytes 1, eosinophiles 1 per cent. Spinal fluid: normal pressure, Wassermann negative, colloidal gold curve negative. Urinalysis showed a few red blood cells and a few white blood cells; otherwise the urine was normal. As the patient was admitted for diagnosis only, no therapy was attempted.

The writer examined the child neurologically November 14, 1929. The examination was unsatisfactory. The child cried perpetually and could not coöperate in the least. He appeared completely demented. He lay in opisthotonos with the legs extended and arms abducted. The pupils were completely dilated as though by homatropine. They were fixed to light. No facial paralysis was present. The cranial nerves were otherwise not satisfactorily examined. The reflexes were not obtainable because of the marked spasticity in all extremities. He moved the arms very little though he could grip with his fingers. The legs were moved freely but were extremely spastic, with adductor spasm. The toes were continually in the position of a positive Babinski. Clonus could be elicited in the right foot. The condition was thought to be probably diffuse cerebral sclerosis. The patient died December 17, 1929.

Postmortem examination.—This was performed about twelve hours after death. The body was that of a fairly well developed, rather poorly nourished baby boy, 88 cm. long and weighing about thirty pounds. Rigor was very marked; purplish hypostasis was present posteriorly. Slight cyanosis was present. There was no edema or jaundice.

The peritoneal cavity was normal. The appendix was free and anterior. The pleural cavities were normal. The pericardial sac was normal; it contained no excess of fluid. The heart weighed 60 grams. All the chambers and valves were normal. There was no anomaly of the vessels. The root of the aorta was normal. The thymus weighed 20 grams and was normal grossly on the surface and on section. The left lung weighed 170 grams, the right 200 grams. Both were nodular and congested throughout and pus could be expressed from both on section. The spleen weighed 40 grams and was normal grossly. The liver weighed 360 grams and was slightly pale; otherwise entirely normal. The gallbladder was normal. The gastrointestinal tract, pancreas and adrenals were normal. Each kidney weighed 40 grams and there was slight cloudy swelling. The bladder and genital organs were normal. The aorta and lymph nodes were normal.

At autopsy no abnormalities of the brain were noticed. The brain was cut into coronal sections at the time and was delivered in this condition to the neuropathology laboratory. Here no gross abnormalities of the surface of the brain were seen. Palpation of the brain substance showed a marked increase of consistency, especially in the white matter underneath the cortex. This increased consistency was not uniformly diffuse but could be felt more under certain convolutions than under others, though there was no tendency for the firmness to be more marked in one or another lobe of the brain. Sectioning the brain with a razor produced the sensation of cutting a sclerotic organ as compared with normal brain.

Microscopic findings.—The accompanying figures illustrate fairly well the essential features of the microscopic pathology. Figures 1 to 4 show Weigert sections of various parts of the cerebral cortex and the basal ganglia. It appears at this low magnification that the myelin sheaths of the centrum semiovale are practically absent. Immediately beneath the gray matter of the cortex is a fine strip of remaining undegenerated myelin sheath fibers following the topography of the base of the cortex. These are arcuate or U fibers of the cortex running from convolution to convolution. It has often been stated that the arcuate fibers are not degenerated in Schilder's disease. However, one sees with the high power of the microscope that not only are the arcuate fibers not degenerated in this area but also the fibers running vertically between the cortex and the centrum semiovale. Thus the preservation is evidently not a system preservation but a regional one with which we are dealing. In Figure 4 the degeneration can be seen extending down into the internal capsule. The fibers of the globus pallidus and putamen are rather markedly degenerated. The fibers of the thalamus appear to be less numerous than is normal. Under the high power the subcortical white matter is seen to be extremely degenerated as regards myelin sheaths with the exception of the arcuate fibers. Only a scattered number of them remains (Figs. 5 and 6). With Bielschowsky's stain for nerve cell processes it is seen that about as many axis cylinders persist as there are myelin sheaths (Fig. 7). Sections of the pons, medulla and spinal cord (Fig. 8 and 9) are of no particular interest excepting that the pyramidal tracts are degenerated as an apparent secondary degeneration and in the medulla the myelin sheaths in general appear to be somewhat scanty.

Cellular stains of the cortex show that the cells of the superficial layers are about as numerous as one ordinarily finds and are well preserved (Fig. 10). The cells in the 6th and in the deeper parts of the 5th cortical layers are less numerous than normally and are undergoing definite degeneration as shown by chromatolysis, fragmentation and nuclear abnormalities. The cells of the globus pallidus are distinctly degenerating and less numerous than normally. In the putamen the cells appear to be about normal. In the thalamus they are apparently moderately decreased in number. The cells of the third nerve nucleus and of the substantia nigra are likewise moderately decreased in number and show degenerative changes. In the medulla the cells are normal except for those of the inferior olive, which are rather strikingly reduced in number; those remaining show only mild evidences of any degenerative process. In the spinal cord the nerve cells appears to be about normal.

Hematoxylin and eosin sections of the white matter beneath the cortex (Fig. 11) show a rather marked increase in the number of glial cells in the region. A large proportion of these glial cells is made up of protoplasmic glia. These cells constitute an unusual picture in that the markedly increased cytoplasm appears homogeneous except at the periphery of the cells, where it is extremely grandular. The granules stain deep red with eosin. Some of these cells appear to have undergone a partial disintegration. Staining by the various silver carbonate methods to bring out the different types of glial cells shows that the vast majority of the glia is made up of astrocytes. The astrocytes have increased in great number and their processes, running in every direction, make a heavy network of coarse glial fibers. It is undoubtedly this increase in astrocytes and their fibers which is responsible for the increased consistency of the white matter of the brain (Figs. 12 and 13). The

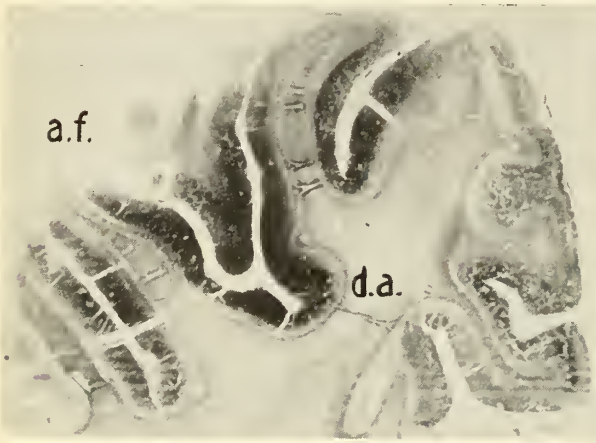

Fig. 3. Left occipital area. a.f.—arcuate fibers. d.a.—degenerated area, the subcortical white matter. Weigert's myelin sheath stain. X 2.

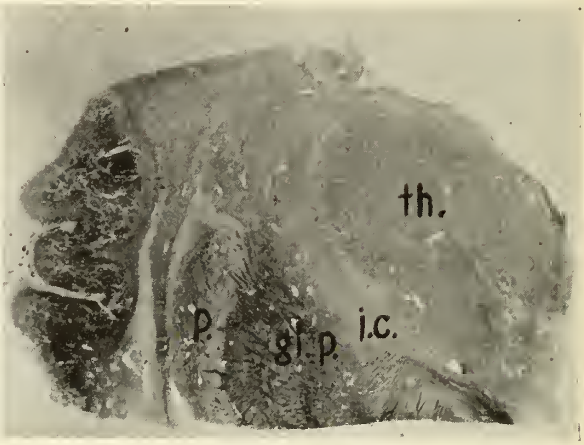

Fig. 4. Right basal ganglia. gl.p.—globus pallidus. i.c.—internal capsule. p.—putamen. th.—thalamus. Weigert's myelin sheath stain. X 2.

increase of astrocytes is most marked in the region of the cortical arcuate fibers which have not yet undergone extreme degeneration.

Various parts of the brain were stained with Sudan III to demonstrate fat. This can be seen piled up in scavenger cells along blood vessels in scattered areas. It can be found in glial cells in small amounts though it is sometimes collected in large amounts in the large protoplasmic glial cells (Fig. 14). Fat-containing glial cells are more abundant in the region of the cortical arcuate fibers than elsewhere in the white matter. Increase of astrocytes in the basal ganglia and likewise in the midbrain is a distinct part of the picture microscopically.

The vessels of the brain show only mild abnormalities. These are evidenced by the collection of scavenger cells in the adventitial spaces along with small numbers of perivascular lymphocytes. The vessels are not thickened and there are no evidences of thromboses. The meninges appear normal throughout.

RECENT CASES FROM THE LITERATURE

Bouman,[3] Collier and Greenfield,[4] Stewart, Greenfield and Blandy,[11] and Globus and Strauss,[6] have reviewed the early literature of Schilder's disease so that it is unnecessary at this point to go over these early cases. These authors together have reported and reviewed about 48 cases. In the present paper I shall review 15 cases that have appeared subsequently to the articles by these writers, or cases which they did not include in their reviews. Together with the personal case reported by me, the total number of pathologically verified cases of diffuse subcortical sclerosis is thus 64. Parts of the following reports are taken verbatim from the former writers. Only those used entire are enclosed in quotation marks.

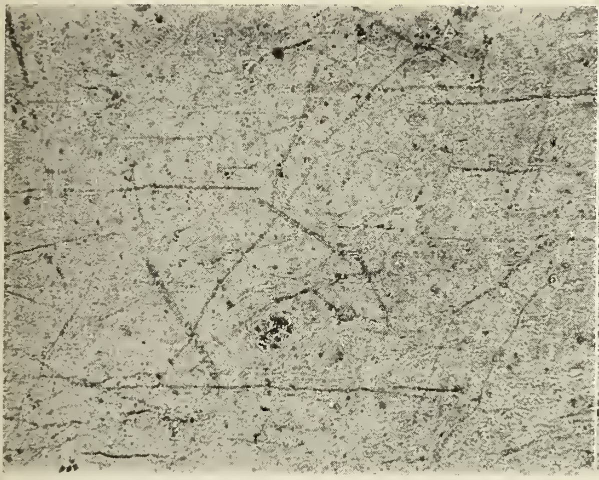

Fig. 5. White matter of left occipital region where myelin sheaths are very sparse. Weigert's myelin sheath stain. Magnification about X 150.

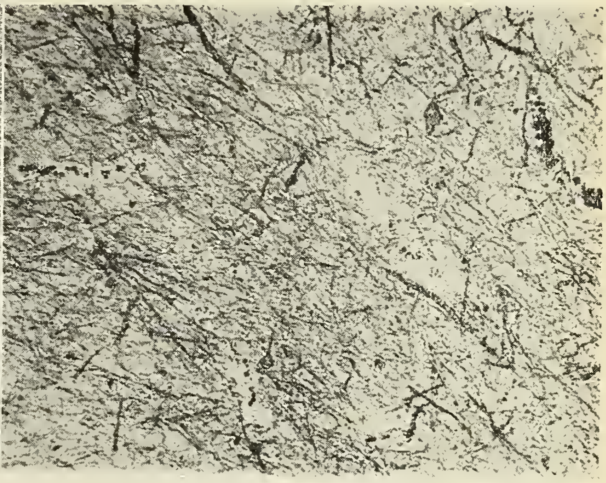

Fig. 6. White matter of left occipital region in the area of the arcuate fibers. Weigert's myelin sheath stain. Magnification about X-150.

No. 1. Schilder,[12] 1924. Female, age 37. One month after an attack of grippe, the patient lost her sense of smell on the left side. Incontinence of urine appeared and the patient developed headaches. She became markedly constipated. The menses of the fifth month after onset were premature. First examination five months after the onset of the trouble. This showed an objective left-sided decrease of smell with negative findings in the nose. Apraxia of the eyelids and to a less degree in the upper region of the face was present. There was a slight right-sided hemiparesis of the pyramidal type. An uncharacteristic tremor of the hand was present, more pronounced on the right side than on the left. The patient tended to fall backwards in a retropulsive fashion, which carried with it, however, a certain apparent voluntary character. Bilateral beginning choked disk was present. Psychically the patient was apathetic, dull and showed a lack of initiative and interest. She was incontinent. A presumptive diagnosis of brain tumor was made and the patient was operated upon. She died about eight months after the onset.

No. 2. Scholz,[13] 1925. This writer has reported the clinical findings of five cases out of a single familial group. Only his second case has been described pathologically. Consequently, it is the only one which will here be summarized.

The hereditary features of Scholz's cases are so complicated that they will not be repeated here. The patient developed normally until the age of eight years, when he became ill with a severe headache and vertigo, with decrease of his mental activity, slowing of speech and spastic paralysis of the extremities, together with a slight sphincter involvement. At the same time he had only a slight decrease of his visual acuity with a correspondingly slight pallor of the temporal halves of the optic disks. Examination early in the disease showed a spastic paralysis of the extremities, slight cranial nerve symptoms and negative spinal fluid. Multiple sclerosis was considered most likely. A half year later he had a total right-sided spastic paralysis with beginning contracture of the fingers and a high grade spastic paralysis of the left side of the body. He also had very evident paralytic phenomena in the cranial nerves and marked disturbances of the sense of touch. Vision had grown much worse; speech was slow and painstaking. Three months later he was completely helpless in bed; shortly thereafter could not speak at all and chewing and swallowing became very poorly performed. He developed severe spastic contractures. One year after the onset he developed attacks of muscle spasm in the extremities associated with crying, apparently because of pain with the spasms. The patient was gradually becoming demented. About three years after the onset he first showed generalized clonic convulsions with loss of consciousness and vomiting over several days at a time with each attack. After four years he no longer reacted to auditory stimuli and gradually became weaker. Was first seen in Scholz's clinic in the second half of the fifth year of the disease. Was now completely demented; reacted only to severely painful stimuli with crying and with indications of flight and protective movements. Neurologically, as concomitant signs of the spastic paralysis, there were increased reflexes, clonus, pathological great toe phenomena. It was noted that on the right a partial, and on the left a total optic atrophy was present. Spontaneous chewing and sucking movements were present and could be brought out by touching parts of the mouth. Swallowing was purely reflex only after touching the soft palate. Also in Scholz's clinic there were noticed painful spasms of the extremities. April 21, 1922, fifteen days after coming into the clinic, he died with bronchopneumonia after an onset four years and ten months previously.

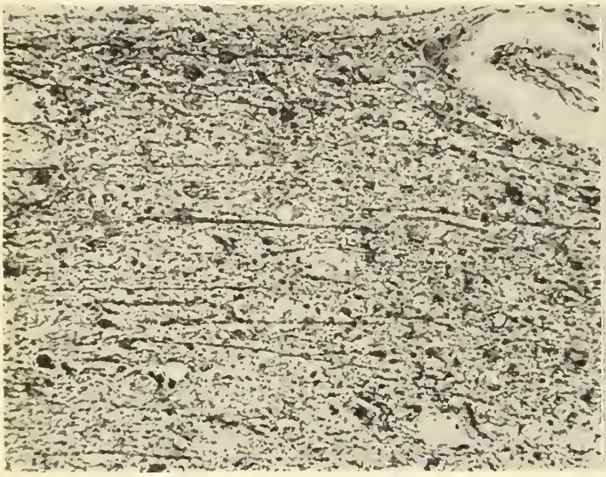

Fig. 7. Deep in the white matter of the right parietal region where myelin sheaths are sparse. For comparison with Figure 5. Bielschowsky's neurofibrillar stain. Magnification about X 150.

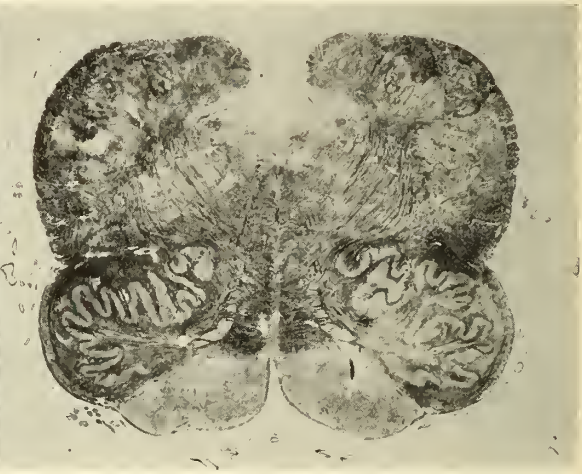

Fig. 8. Medulla oblongata. The pyramidal tracts are markedly degenerated. Weigert's myelin sheath stain. X 4½.

No. 3. Kraus and Weil,[14, 15] 1926 and 1928. Case was that of a Hebrew tailor, born in 1877, whose family and past history were unimportant. In 1911 while walking in the street, the patient suddenly fell to the ground helpless and could not get to his feet again without assistance. There were no convulsions and no loss of consciousness. Sensory disturbances, ataxia, and anesthesia to touch were noted in all four extremities, but disappeared after a few weeks. The cranial nerves were normal with the exception of slight deviation of the protruded tongue to the right. In December, 1911, there was slight concentric contraction of the visual fields. At this time he also showed: diminished sense of smell; a slight tremor of the hands; ankle clonus which was persistent on the right, exhaustible on the left; persistent knee clonus on both sides; the upper abdominal reflexes were present, the lower were absent on the left; a pseudo-Babinski sign on the right and markedly exaggerated knee jerks; no ataxia; occasional incontinence of urine. Condition remained unchanged for five years. He was re-examined in 1921, at which time the same neurologic status was revealed, with an increase of the eye disturbances, insufficient convergence of the right eye, weakness of the rectus internus and externus on both sides, irregular pupils with reaction to light but none to accommodation. The right arm was weaker than the left and the biceps and triceps reflexes were lively on both sides. There was slight ataxia of the left arm, marked ataxia of the right, and ataxia of both lower extremities with loss of sense of position of the toes. A marked Romberg sign was present. There were no sensory changes. The gait was peculiar; it required a cane and was characterized by small steps and shuffling of the feet. Every time the foot touched the floor there was hypertension at the knee. Speech was very rapid and scanning with a peculiar repetition of the last word of each sentence. The condition was progressive and in July, 1923, the patient could not stand or walk. There was a mild degree of dementia. In March, 1924, complete left hemianesthesia was noted. In June, 1924, the patient died after an acute attack producing left-sided convulsions and anesthesia.

No. 4. Ferraro,[5] 1927. Case 1. Woman. Age at death in 1925, 32. Onset in 1913 at the age of 20, following a severe burn. Behavior has been queer since then. She thinks someone has cast a spell over her. She refuses to wash or bathe herself or to comb her hair. She is forgetful, leaves the change on the counter, talks in her sleep and to herself; is a spiritualist. In 1919 it was noticed that she was somewhat intellectually and emotionally deteriorated; knee jerks very active; pupils dilated, rather irregular, sluggish to light, especially on the right; decided Romberg present; tremor of the facial muscles and fingers; speech ataxic; gait shuffling; Babinskis negative; no sensory disturbances; mild leukocytosis of the spinal fluid; Wassermann on blood and spinal fluid repeatedly negative.

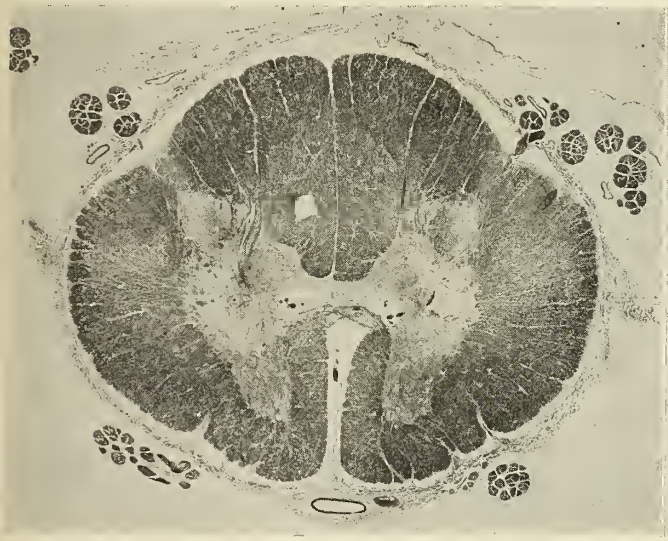

Fig. 9. Upper lumbar cord. Pyramidal tract degeneration. Weigert's myelin sheath stain. X 9.

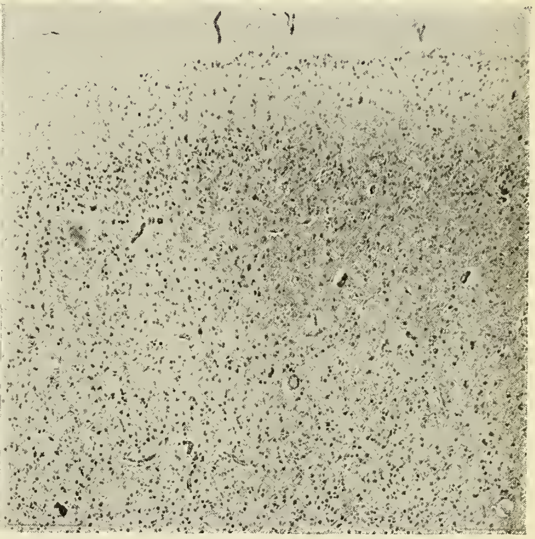

Fig. 10. Right parietal cortex. Thionin. Magnification about X 16.

The patient's parents were separated. Two brothers are said to have had "multiple sclerosis" (see the following two cases). Maternal grandmother insane, maternal cousin feebleminded. The patient was backward in school but social life normal. The neurologic symptoms progressively increased. In January, 1925, she was anemic and weak and had developed severe bed sores. Her speech was monotonous and sing-song. There were involuntary grimaces and distortions of facial muscles. Intention tremor was very marked. There was no nystagmus. She died in 1925 with a clinical diagnosis of multiple sclerosis.

No. 5. Ferraro,[5] 1927. Case 2. The patient was a brother of case 1. He was born in 1889. Except that he had never held a position for very long, his past history was essentially negative. He was drafted into the army in 1918. While at camp, about July 1, 1918, he began to be lame. He felt nervous at this time. Was discharged from the army as physically unfit in August, 1918.

While in the army camp he had begun to develop a paranoid trend. After leaving the army, he began to hear hissing noises in his ears and later had actual auditory hallucinations. He also began to have at this time explosive outbursts of laughter. He entered Belview Hospital at his own request in September, 1919, claiming that he felt nervous, that he was very emotional and that his memory was not so good as formerly.

Examination showed the pupils somewhat irregular, but reaction to light was fairly prompt, though diminished in extent; the eyes were somewhat unsteady when he looked to the extreme right or left, but no clearly marked nystagmus was present. There was bitemporal pallor of the optic disks with contraction of the arteries and veins. His hearing was rather dull and he complained of a loud hissing in both ears. Cremasteric and abdominal reflexes were difficult to elicit though not entirely absent on either side. Babinskis negative. Muscular strength poor, but equal on both sides. The left side of the face was slightly flatter than the right, the tongue deviated slightly to the left, the gait was unsteady with the feet occasionally scraping the floor when walking, especially on the left side. All the muscular movements were clumsily performed, though the sense of position was not lost. Romberg sign negative. The fingers, tongue and lips were all fairly steady. No definite speech defect. Blood and spinal fluid Wassermann negative. Globulin + + in the spinal fluid. The first spinal fluid test showed one cell, the second showed five.

Mentally the patient was dull and indifferent. He said that he felt depressed at times, but qualified this by saying he felt cheerful even when he was sad. He often laughed in a silly manner which he could not control. He still had hallucinations, memory was good for both recent and past events. He seemed rather childish and his judgment was poor. He died March 30, 1924, of bronchopneumonia. The neurologic diagnosis was multiple sclerosis.

No. 6. Ferraro,[5] 1927. Case 3. The patient is the brother of the two first cases. He was born in 1884.

No serious abnormalities of his development were noted until nineteen years of age, when he ran away from home. He stayed away for two years, working about the country in various places without much progress. At the age of twenty-one he fell a distance of sixteen feet, landing on his back. A week later he had difficulty in walking. His foot appeared to be paralyzed and he had a staggering gait. He also became nervous and had spells of involuntary laughter. He was placed in a hospital, where he was somewhat hypochondriacal. He laughed without cause and explosively. The general examination was negative except for a slight dullness and prolonged expiration over the apex of the right lung. Urinalysis was negative. The tendon reflexes were all greatly increased. Ankle clonus present on both sides. Babinski phenomenon present on the right side. Superficial reflexes were absent. Station was good but the finger-to-finger and finger-to-nose tests were badly performed. His gait was stiff and awkward. The pupils were dilated and reacted to light and accommodation. He was unstable emotionally and seemed to be fluctuating between depression and exhilaration. On one or two occasions he threatened suicide. He was then paroled from the institution. In 1909 he developed a trophic ulcer on the left anterior tibial surface. In 1910 his health was fairly good and mentally he was in exactly the same condition as previously. The neurologic examination was the same as formerly except that the Babinski tests were positive on both sides, the gait was spastic in type, there was marked incoördination of the movements of the lower extremities, a coarse tremor was present which became more marked when fine movements were attempted. The speech had also become jerky in character and was termed scanning. In 1911 it was noted that he had become more unsteady in walking and occasionally fell. In 1912 he developed bowel and bladder incontinence. A spinal fluid test was done in May, 1914. The Wassermann, gold sol reaction and Nonne were negative. Cell count, 58 per cubic mm. Blood Wassermann, negative. He developed large bed sores and gradually became weaker until the time of his death, Oct. 26, 1916.

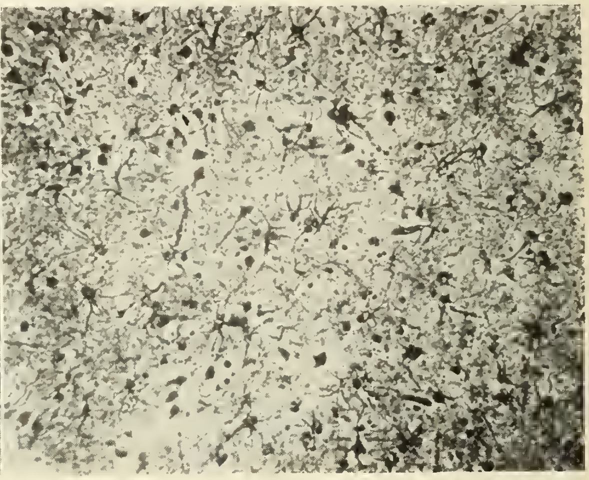

Fig. 12. White matter of left frontal region. Numerous glial astrocytes present. Hortega's silver carbonate stain for astrocytes. X 100.

No. 7. Schaltenbrand,[16] 1927. "A girl, aged 14, came into the clinic because of headaches and pain in the right lower abdominal quadrant. The patient's mother has a depressive climacteric psychosis and the grandmother has suffered for years from a paranoid psychosis. On admission the patient was apathetic. She had a right facial weakness and hyperemia of the optic disk. During the next few weeks, she developed hypotonic right-sided hemiplegia, hypesthesia for touch and pain over the whole right side, right hyposmia, and left homonymous hemianopia. Shortly afterwards, a motor and later also a sensory aphasia appeared. The choking of the disks gradually increased during the next few weeks to from 4 to 5 diopters. Meanwhile the left leg became paralyzed, and all the paralyses slowly acquired a spastic character. The right arm went into flexion contraction. The head and eyes became strongly deviated, at first to the right and later to the left. Finally, the patient became entirely blind, aphasic and almost completely paralyzed, though in the left arm certain movements, athetoid in character, put in an appearance."

"One lumbar puncture gave negative results; another, a slight increase of globulin and 10 cells. The blood picture was normal, with the exception of a slight leukocytosis. The patient grew worse in spells which were accompanied by a subfebrile temperature. The disease lasted three months altogether."

No. 8. Bielschowsky,[2] 1927. The patient was born in 1868. His family history showed that his antecedents were a nervous type, otherwise normal. He, himself, is said to have had a tendency to fits of rage in the past. As a youth he had a middle ear inflammation with subsequent decrease in his hearing. Otherwise was well until the period 1918 to 1920, during which time without apparent cause all of his teeth fell out. In September, 1920, at the age of 52, he was sick for ten days with fever, chills, joint pains and lassitude. Three weeks later he again had a febrile illness. He is said to have had yellow scleræ. The sickness was first considered malaria and then later an intestinal intoxication. There were no nervous symptoms. The patient has been impotent since this illness. In 1923, he was denied coverage for life insurance because his pupils had become unequal and reacted poorly. Later special investigation did not substantiate this finding. In June, 1924, he had another attack of febrile illness which lasted off and on until the first week of July. August 8, 1924, he was again taken sick, with confusion, weakness, inability to speak. The following day his temperature rose 1° to 2° C and he recovered on the fourth day. Examination on the fifth day was negative neurologically except for a positive Oppenheim reflex on the left. There was a hypalgesic zone on the left leg and a hyperalgesic zone at the nipple level running around the trunk. The patient swayed somewhat in turning abruptly on his feet even though his eyes were open. The visceral examination was essentially negative except that the liver edge could be palpated. Blood counts normal, no malaria, the Wassermann reaction normal. August 11 the sensory disturbance in the left lower extremity disappeared and the liver edge could no longer be palpated. September 1, 1924, he came home extremely tired and much agitated; the next day he complained of headache; the temperature was normal. September 3, he had an afternoon temperature of about 1° C. He complained of severe headaches, he was very difficult to awaken in the evening and was quite stupid. September 4, the temperature was 39.2° C. Slept most of the time, could be awakened, however; had a nearly complete motor and sensory aphasia. He could not even say his own name at times. When he did speak he used Spanish, though his mother tongue was German. An exact examination was impossible. He appeared not only temporally and spatially disorientated but also apractic. He was negativistic and incontinent. In the afternoon his sensorium was entirely clear. He had a slight paraphasia and perseveration. Examination was essentially negative, excepting that he had evident though not very marked spasms. The Babinski and Oppenheim signs were positive on the left and the abdominal reflexes were weaker left than right. He had a complete amnesia for the time of fever. September 5, he had slight spasms in all the extremities, especially in the adductors of the thigh, so that he had a cross-legged progression. He could take a few steps with help, but tended to fall backwards with the eyes open or closed. His gait was ataxic. There was no ataxia in the arms. He could not tell when his bladder was full and recognized that his water was passing only when the skin of his thigh became wet. September 8, felt perfectly well. Was examined eight days later by Professor Cassirer, who found absolutely nothing wrong with the patient. On September 25, after having meantime worked at his profession as an engineer, he came home complaining of weakness and appeared rather dull. He complained of severe headache, was restless during the night, an exophthalmos appeared, he was incontinent and during his attack bit his tongue. His left arm went into a definite convulsive movement. This lasted ten minutes and he had a second attack later in the night. Was taken to the hospital and his mental condition cleared up during transportation to the hospital. Two hours later he became somnolent, vomited and, although he seemed clear mentally, he occasionally could not find the word for which he sought. Examination September 26: General examination negative. Skin negative. The scleræ show a slight subicteric tinge. The pupils were slightly unequal, possibly somewhat irregular. The right pupil appeared to react somewhat slowly to light. Abdominal reflexes absent; two hours later, present. The left one was, however, the weaker. Sensation normal excepting in the left mammillary zone where sensation for sharp and dull was decreased. Definite rigidity present in

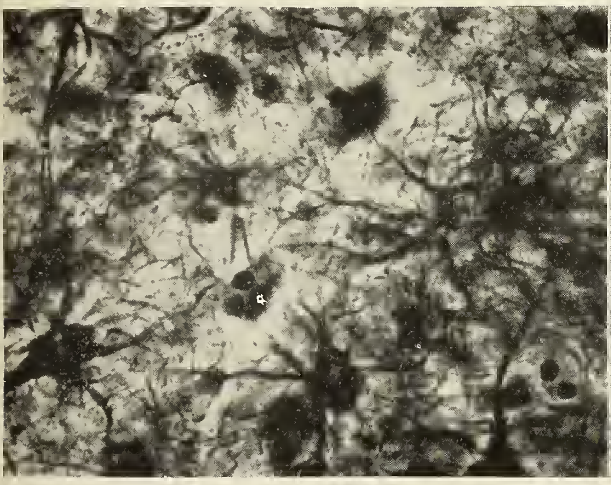

Fig. 13. Same area as in Figure 12. The coarse ramifying fibers of the astrocytes make a dense network. X 400.

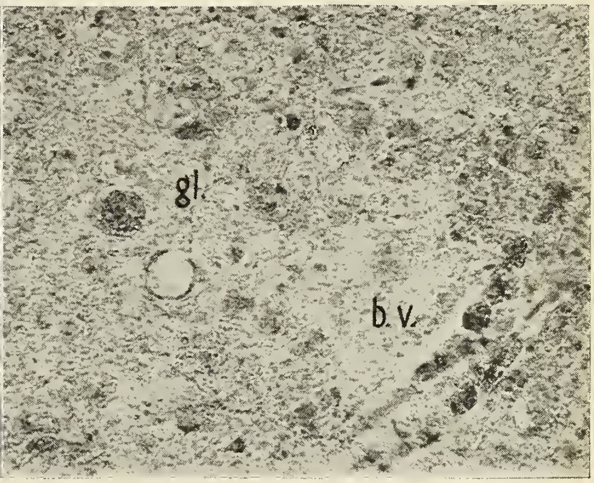

Fig. 14. White matter of frontal region. Sudan III stain for fat. gl.—protoplasmic glial cell filled with fatty granules. b.v.—blood vessel with a row of fat-filled scavenger cells in the perivascular space on either side of the vessel. X 300.

both arms, left more than right. Definite rigidity in the left leg. There was an area of decreased sensation to sharp and dull over the left tibia and dorsum of the foot. Lumbar puncture revealed a high cell count. There was a gold sol reaction in the first zone. Complete recovery by October 3. November 1 he again had fever, was unconscious and was taken to a hospital in Baden Baden, where a presumptive diagnosis of brain tumor was made, but because of the lack of a definite localization, no operation was undertaken. He was in coma for three days and died November 4, 1924.

No. 9, Gagel,[17] 1927. A boy eight years of age. After an attack of measles he developed a decrease of his mental faculties, was uninhibited and had a spastic paretic gait. The condition grew gradually but steadily worse. His intelligence decreased so that calculation, writing and reading became impossible. About three-quarters of a year after the onset there were high grade spastic phenomena in all four extremities. In about one year the patient stopped speaking. He did not react to external stimuli but only waved his arms here and there in an athetotic fashion. He then developed great difficulty in swallowing and died one and a quarter years after the onset, with pneumonia. His previous history had been essentially negative.

No. 10. Foix and Marie,[7] 1927. Patient, aged 63, had a spasmodic clubfoot since infancy. This condition appeared with convulsions at the age of a few months, after which the deformation of the right foot appeared. The foot at the time of examination was in the varus equinus position. There was a limitation of movement in dorsiflexion of the foot, although strength in the anterior leg group of muscles appeared normal. There was a considerable muscular atrophy, more marked in the extensors of the legs. Knee jerks active; the Achilles reflex could not be elicited, probably because of the contracture. Babinski sign positive. Anatomically there was found an era of centro-lobar localized sclerosis at the upper part of the left cerebrum. This sclerosis ramified throughout the considerable part of the left cerebral hemisphere's white matter. Microscopically it consisted of adult neuroglia tissue and Foix and Marie are inclined to interpret the condition as an encephalitis periaxialis diffuse which has come to a standstill.

No. 11. Liebers,[8] 1928, has summarized the clinical history of a patient, previously described by Merzbacher under the name of aplasia axialis extracorticalis congenita. The case was that of a girl who came from a remarkable family in that all told it included fourteen known cases of the disease. In the case of the patient in question the disease began in the third or fourth month of life with shaking of the head and eyes. Then there appeared gradually increasing spastic contractures of both the upper and lower extremities with positive Babinski and a fixed expression to the face, nystagmus, scanning speech, tremor and choreo-athetoid movements. Because of the increasing contractures and an osteoporotic involvement of the skeleton with deformities of the thighs, the patient finally became permanently bedridden. There were no sensory disturbances. The intelligence was only slightly involved. Death came from an intercurrent pulmonary involvement. While Liebers keeps this case separate from the other cases of diffuse cerebral sclerosis and designates it as the Pelizaeus-Merzbacher disease, it seems to me more likely that the condition is simply one in which the heredo-familial factor stands out extremely prominently. The pathology conforms fairly well to that described for the other cases of Schilder's disease.

No. 12. Bielschowsky and Henneberg,[10] 1928. Case 1. The birth and early development of the patient, a boy, were normal. Without recognizable cause he became ill at the end of his eighth year of life, with decreased hearing and spasms in the legs. The course of the disease was rapidly progressive. After two months a high grade decrease of vision already existed due to optic atrophy, and there were also severe spasms in the lower extremities. The reflexes were bilaterally spastic, more marked on the right side than on the left. After two months more there was blindness and severe loss of hearing. It seemed, however, that there was greater difficulty in the understanding of words than actual decrease of auditory acuity. Then rapidly appearing dementia occurred and the patient stopped playing, he cried incessantly, was incontinent, and ceased speaking. He also deteriorated markedly from a physical standpoint. Eleven months after the onset he was in a terminal state and there were severe spasms of the arms and legs, fixed pupils, optic atrophy, loss of the corneal reflexes. Spasms were more pronounced during spells of crying. Blood and the spinal fluid were normal. Death occurred in a cachectic state after a period of illness of not quite one year.

No. 13. Bielschowsky and Henneberg,[10] 1928. Case 2. The patient was the brother of the former patient. Normal birth. As a small child had attacks of laryngospasm and also temper tantrums, "Wegbleiben." Later there were pavor nocturnus and somnambulism. The disease began at ten and one-quarter years of age with decrease of hearing. Also in this case the auditory aphasia seemed considerably more marked than the decrease of hearing itself. Nine months after the onset there was disturbance of vision evidently due to optic atrophy. After one year spasms appeared in the lower extremities. At that time the mental condition was still good. Trepanation and inunction treatment had little effect on the course of the disease. One and a half years after the onset there appeared a series of epileptic attacks followed by a condition of unrest and confusion. During the months just previous to death the following symptom-complex appeared: blindness with advanced optic atrophy, complete deafness, extensive feeblemindedness, spastic paresis in the extremities, athetoid movements of the arms, increase of reflexes (though there was at the same time absence of the left knee jerk and decrease of the lower abdominal reflexes), periodic attacks of crying and laughing. Death occurred at the age of twelve and three-fourths years in a cachectic state.

No. 14. Sheldon, Doyle, and Kernohan,[18] 1929. Case 1. A boy aged 7, was admitted to the Mayo Clinic June 6, 1926. Ten weeks previously the parents had observed that the child was growing deaf and becoming somewhat apathetic. Six weeks previously it had been noted that his eyes no longer converged and that he stumbled and seemed clumsy. Three days before admission he fell to the floor. He rose only to fall again in a similar manner. The legs began to twitch and the arms and face were successively involved, while the eyes turned upward and to the left. Convulsions were controlled by ether. On regaining consciousness after the anesthetic he was blind and complained of frontal headaches which persisted for twelve hours. The following day he had another convulsion and then vomited about twelve times during the next twelve or fifteen hours. The vision and general condition then improved rapidly. On examination he was found to be partially deaf, but he also failed to understand much of what was said to him when he could hear. He could read moderately large print. Perimetric examination could not be performed. Fundus negative. Neurologic examination showed slight vertical nystagmus when the patient looked to the left. Convergence absent. The pupils were dilated and reacted to light and accommodation. There was suggestion of partial paralysis of the lower portion of the right half of the face with associated movements of the fingers and toes on the left side. The right patellar and Achilles reflexes were somewhat exaggerated and Babinski's sign was present bilaterally. The abdominal reflexes were not obtained. Vibration sense was lost over both malleoli. There was incoördination on the finger-to-finger and heel-to-knee test, particularly on the left side. The gait was somewhat ataxic and slightly spastic. Spinal fluid negative except for a curve in the colloidal benzoin test in the middle zone. *X*-ray studies, urinalysis, blood counts, Wassermann reaction and urea content of the blood were all negative. The patient had a suppurative otitis media on the right side which cleared up under treatment. Condition was unchanged until July 12, when he vomited several times on arising, complained of severe headache and expressed fear of dying. He then had a slight general convulsion, was stupid and confused afterward and occasionally cried out as in pain. Several attacks followed in the course of the next few hours. Was taken to a hospital, where he appeared dull and exhausted though he tossed about restlessly He soon became noisy and violently resistive, thinking he was being poisoned. Consciousness was partly regained the following morning. He was blind at that time. During the day he became more rational and the vision improved. July 16 preservation of speech was noted. He was more emotional. He was totally deaf and continued having convulsions. Ventriculography was performed July 30 and it was noted that the subcortical cerebral substance was resistant to the passage of the cannula. Grew steadily worse; by September 15 he was unable to walk; control of the arms and legs was gradually lost and about October 10 he became unable to speak. Early in November he had difficulty in chewing and in moving the tongue. Subsequently dysphagia developed. He died November 26, 1926.

No. 15. Sheldon, Doyle and Kernohan. Case 2. "A woman aged 27 was admitted to the Mayo Clinic June 29, 1927, complaining of blindness. She had always been well and strong. Six and a half weeks previously she had been delivered of her first child by forceps. Two days later, a foul vaginal discharge was noted, and fever and malaise set in and persisted for three weeks. Four weeks before admission the patient had noted slight blurring of vision which progressed to complete blindness in the course of a week. Subsequently her general condition improved considerably."

Examination showed complete blindness, dilated pupils, slight optic neuritis, partial paralysis of the lower part of the left half of the face. The laboratory tests were negative. By July 2, the patient became slightly stuporous and complained of nausea. She had a generalized tremor, the facial paralysis was more marked, the tendon reflexes were increased on the left side and she was involuntary. By July 5 she had a complete left-sided hemiplegia and was in coma. The spinal fluid pressure was 300 mm. of water. Cerebral abscess was suspected. She was operated upon July 5 and died July 9.

The gross pathology of this case does not conform to the ordinary picture of "Schilder's Disease" and certain features of the microscopic pathology are atypical.

THE CLINICAL AND PATHOLOGIC PICTURE

Schilder has summarized his investigation of 1912 as follows:

"1. First, there is a diffuse disease of the white matter of the cerebral hemispheres, occurring in childhood, which one is justified in considering as a separate disease on the basis of a characteristic macroscopic and microscopic pathology. I propose the name encephalitis periaxialis diffusa for this disease."

"2. The clinical picture of the disease is a very inconstant one. It occurs now under the picture of a brain tumor, and again under the picture of multiple sclerosis, and further under the picture of diffuse sclerosis of the type Heubner. One will naturally suspect the existence of the disease if the symptoms indicate an extensive lesion of both hemispheres. Rapidly developing cases of the symptomatology of multiple sclerosis at an early age of the patient will likewise suggest the possibility of this disease. The disease is fatal and the course has only a slight tendency to remission."

"3. Encephalitis periaxialis diffusa stands closely in relationship pathogenetically to multiple sclerosis, and especially closely to the acute forms of multiple sclerosis. Also for this disease there must be assumed a toxic effect on the brain. It has no relationship whatsoever to pseudosclerosis, tuberous sclerosis or to a certain number of the cases of so-called diffuse sclerosis."

"4. The etiology is still unexplained. Probably endogenous factors favor the development of the disease. The morphological findings do not support the assumption of an abnormal embryologic development of the brain."

Globus and Strauss[6] described the clinical group as follows:

"Thus an abrupt onset, a rapidly progressive course, characterized by mental deterioration, rapidly advancing spastic paralysis, epileptiform attacks, features of decerebrate rigidity, ocular palsies and other ocular manifestations such as nystagmus, optic atrophy, and blindness without optic atrophy followed by a rapid decline with fatal issue (within two years) are fairly typical."

Collier and Greenfield[4] have outlined the clinical aspects of the condition as follows:

> "A malady usually occurring in children and young subjects with no tangible causal factors or antecedent experience. The onset is a few days, the course progressive and some remission to a fatal issue, the duration from a few months to three years. The chief early sign is cerebral blindness which becomes complete, to which is added mental reduction and increasing spastic paralysis. Unsteadiness from parietal involvement and deafness from temporal involvement may be conspicuous. The amentia increases and passes into coma, which terminates the illness. The condition, usually bilateral, may commence on one side or may be confined to one side."

As Bouman's[3] observations and literature citations show, the foregoing statements of the clinical syndrome are inadequate in that so many other symptoms may appear that one is left with no very satisfying concept of the clinical picture of the disease. For instance headache, vomiting, incontinence and fatigue were found in the majority of the cases that Bouman reviewed. Epileptiform attacks were common. A few of the cases showed choked disk. Tonic and clonic convulsions occurred in several of the cases. Pupillary anomalies occurred. There was Argyle-Robertson sign in one. Strabismus, diplopia, disturbances of the conjugate movements were common. Transitory paralyses were noted. The tongue was commonly partially paralyzed. Intention tremor occurred. Then, too, while most of the patients are young, the condition is by no means limited to infancy or childhood.

Cases such as that reported by Bielschowsky[2] and reviewed in the present paper as No. 2 in the series reported from the literature, do not fit into the clinical picture at all as it is usually conceived.

It is evident in reviewing the literature of the condition that a clinical diagnosis of diffuse cerebral sclerosis can be made only in a certain percentage of the cases. The condition will frequently be confused with brain tumor, with multiple sclerosis and possibly with syphilis and arteriosclerosis.

Pathologically the findings in most of the reported cases conform reasonably well with those in the present material. However, the pathology of the condition as described by various writers is not always uniform. Sheldon, Doyle, and Kernohan's[18] case 2, Foix and Marie's[7] case and others show this lack of conformity. Of course, no two cases are absolutely identical, but in general, subcortical diffuse demyelinization with astrocytic glial overgrowth in the region, secondary degeneration of the pyramidal tracts and more or less preservation of the subcortical arcuate fibers are the principal pathologic characteristics of the condition.

NOSOLOGICAL CONSIDERATIONS

Several attempts have been made by various writers to properly classify the various conditions grouped together under the term diffuse sclerosis. Neubürger has proposed the following subgroups under diffuse cerebral sclerosis: First, a blastomatous or neoplastic; second, an exogenous inflammatory; and third, an endogeneous degenerative. As Bielschowsky and Henneberg have stated, however, the blastomatous group is a very weak one nosologically. While it is conceivable that a glioma might infiltrate a very large portion of both hemispheres of the brain, it is unlikely that such a tumor would limit itself to the white matter alone, producing degeneration of the myelin sheaths with relative preservation of the nerve fiber processes themselves, however, and then evidence itself as a sclerotic process, as scar formation, instead of showing the many types of young glial cells which one usually sees in a glioma. In other words those cases of so-called diffuse sclerosis which have been considered neoplastic are to be looked upon with a good deal of suspicion as being probably not neoplastic.

Schilder's term encephalitis periaxialis diffusa implies an inflammatory basis for the condition. His original case is in itself not at all conclusive either in the clinical course or in the pathological findings of an inflammatory condition. Probably the most outstanding case in the literature which could be classified as inflammatory diffuse cerebral sclerosis is the one reviewed in the present paper as reported by Bielschowsky. But even here, though the clinical findings are extremely suggestive, the pathological picture is by no means conclusive of an inflammatory process. Of the so-called inflammatory cases, while admitting the possibility of such a group, there is a dearth of good illustrative material and we are totally in the dark regarding any satisfactory designation of the etiologic factors which may underlie the inflammatory production of the diffuse sclerosis in any one case.

To state that a condition is endogenous and degenerative is applying a name to it which does not carry much force unless we can indicate the factors, endogenous or degenerative, which produce the condition. The only obvious endogenous factor which has been satisfactorily pointed out in the literature of this condition is the hereditary factor. The case presented in the present article is probably a member of this group. Bielschowsky and Henneberg have reported hereditary cases. Ferraro, Krabbe and others have also given us examples belonging to this group.

Though one may have difficulties in a given case in the clinical differentiation of diffuse sclerosis from multiple sclerosis, with the rare cortical sclerosis such as has been reported by Rusk and Nixon,[19] with tumors and probably with certain other conditions, the clinical and pathologic picture as a whole is sufficiently definite to permit its separation from other sclerosing entities. In the light of what has been stated in the foregoing it seems to me that a simple terminology is still usable. The terminology should be on a descriptive basis because of our lack of knowledge of the etiologic factors except heredity.

A simple classification follows.

In order to designate the group of conditions falling under the general heading one might use the term *Diffuse Subcortical Sclerosis.* "Subcortical" is more accurately descriptive than "cerebral."

Under *diffuse subcortical sclerosis* then one could place three general types: 1. *Inflammatory type.* 2. *Hereditary* or *familial type.* 3. *Primary* or *essential* or *non-hereditary* or *sporadic type.*

1. The *inflammatory type* would include such rare cases as Bielschowsky's.[2] In those cases where the inflammation is due to a well-known etiologic inflammatory entity, the diagnosis of diffuse subcortical sclerosis should not be used, but the diagnosis should be that of the primary inflammatory condition.

2. The *hereditary* or *familial type* would include such cases as that reported in this paper, Bielschowsky and Henneberg's, Scholz's, Krabbe's cases and those of the so-called Pelizaeus-Merzbacher disease. Bielschowsky and Henneberg suggest the subdivision of this group into an *acute infantile* (Krabbe), a *subacute juvenile* (Scholz), and a *chronic type* (Pelizaeus-Merzbacher). In the light of the small number of cases and the lack of good definition between these forms it seems to me unnecessarily complicated to make these distinctions.

3. The *primary* or *essential* or *non-hereditary type* would include those cases of diffuse cerebral sclerosis identical with those of the *hereditary* or *familial type* but lacking the hereditary factor. The occurrence of sporadic cases of hereditary diseases is a common observation in any larger medical clinic. No doubt, therefore, many cases that might naturally be placed in this category really belong with the *hereditary* or *familial* type. Possibly, if our knowledge of family histories were complete, we would be in a position to do away with the *primary* type altogether.

SUMMARY

1. A case of diffuse subcortical sclerosis of the familial type is presented clinically and pathologically.

2. The case reports from the recent literature of this and allied conditions are summarized.

3. The confusion of classification and terminology is **pointed out.**

4. A simple classification is suggested as follows:

(a) The term *diffuse subcortical sclerosis* is a satisfactory designation for the general group. The subgroups are:

I. Inflammatory type.
II. Familial—hereditary type.
III. Primary or sporadic type.

LOCALIZED ACTINOMYCOSIS*

H. B. Zimmermann, M.D., F.A.C.S.
Miller Clinic
St. Paul

IN 1875 Cohn described a filamentous organism obtained from a lacrimal duct abscess, which he called a streptothrix. Bollinger in 1877, in collaboration with Hartz, the botanist, described a new fungous disease of cattle. Because of the ray-like arrangement of mycelial threads of the fungus, they called the condition actinomycosis.

Israel in 1878 reported from the Jewish Hospital in Berlin three cases of a chronic, localized, pyogenic disease in human beings. He gave an excellent description of the pathologic process and what he took to be the causative agent, a mycotic fungus with micrococcus-like bodies. These micrococci, he said, were either forms of the fungous growth or organisms which grew symbiotically with the fungus. Cohn was permitted to study Israel's organism and he identified it as the same as that described by him three years before.

Eppinger in 1890 studying the cultural characteristics of the ray-fungus, attempted to find evidence of the production of a soluble endotoxin, but with negative results. Harbitz and Grondahl, in 1911, studied eighty-seven cases of actinomycosis giving special attention to the source and mode of infection. They found many types of actinomyces occurring in nature, but none resembling those recovered from the lesions in man, a specific anaërobic actinomycete (actinomyces hominus). Wright, Shiata and others came to the same conclusions.

The occurrence of five cases of localized actinomycosis in my own practice in two years suggested this presentation. In most of my cases the patient had to do with the handling of cattle, and two gave definite histories of the entrance of a piece of grass or barb of barley in the exact location where the lesion ultimately developed. It is quite possible that the infection is transferred from one infected animal to another through the contamination of grass or hay, the entrance of such a foreign body making an ideal anaërobic inoculation.

Actinomyces are found in nature and can easily be cultured from plants and grasses, or their spores recovered from the air. In every instance these organisms are found to be of the aërobic type, producing in their growth, aërial hyphæ, whereas the pathogenic type is constantly anaërobic and grows only beneath the surface of the medium. The pathogenic organism has been found only in its animal hosts, but the presence of bits of grass or hay in the lesions has been considered by many as conclusive evidence that these were the carriers of the infection.

The lesion of actinomycosis is a very constant one, the focus of infection always essentially a granuloma. Depending on the age and location of the granulomata, they vary in size from that of a pea to large irregular masses often connected with one another by fistulous tracts lined with the same tissue. The lesions contain very little fluid pus and almost no necrotic tissue. The amount of tumefaction about the lesions is dependent on their location. If situated in the neighborhood of fascial planes there will be an enormous amount of fibrous tissue converting the entire region into one homogeneous mass. On making a section through such an inflammatory area it will be found to be made up of the various types of tissue, such as muscle, fibrous tissue, and, when in that location, salivary gland. The infiltration with new-formed fibrous tissue is of such uniform hardness that the normal cleavage planes are entirely obliterated. Somewhere within this mass will be found one or more granulomatous masses made up of soft, red, pulpy granulation tissue, and, if there is no secondary infection, only a slight amount of pus. If one searches diligently an occasional sulphur granule will be found.

Obviously the symptoms vary according to the location of the lesion. Patients ordinarily suffer very little from the presence of such an inflammatory process. In lesions about the face or neck there may be neuralgic pain from involvement of the sensory nerves, or stiffness of the neck or trismus if the muscles of mastication are involved. Variation from the normal blood-picture depends entirely on the presence or absence of secondary infection.

---

*Presented before the Western Surgical Society, Del Monte, California, December 13, 1929.

The most frequent type of infection is the cervico-facial form. In the typical advanced case of this type of infection the inflammatory mass extends from the parotid region into the submaxillary triangle. The swelling of the neck often extends beyond the line of the jaw, the skin being shiny, purplish in color, and the entire involved tissue of wooden hardness. There may be superficial, fluctuating areas or depressed fistulous openings, and often scars from previous incisions. In lesions as extensive as this there is regularly trimus from involvement of the muscles of mastication.

In regard to the diagnosis of actinomycosis, it may be said that any indolent, chronic, indurative, inflammatory process should be under suspicion, but the only positive diagnostic finding is the discovery of the ray-fungus in the sulphur granule. These sulphur granules are not as common as one might expect, and we have seen cases that were treated as being actinomycosis, with a moral certainty that the diagnosis was correct, in which sulphur bodies were never found. In one instance, the first time the patient was seen a sulphur granule was expressed from the fistulous opening, and although the entire mass was radically excised and submitted to careful examination, additional ones were not discovered. Unfortunately, although these organisms can be grown *in vitro*, it is almost impossible to grow them from the tissue or any other material than the sulphur granule itself. Therefore, cultures are of no value, since, if the granule is found, the diagnosis can be made immediately by microscopic examination of the unstained material. To make the microscopic diagnosis one must be able to demonstrate the ray-like arrangement of the club-shaped bodies, for other large organisms, notably Vincent's, tend to form yellowish clumps. The long fusiform bacteria can easily be confused with the mycelial threads of the ray-fungus, especially if one is prejudiced.

The treatment of actinomycosis should be a definite and very radical procedure, and the clinical and pathological pictures are quite constant. Even if the fungus cannot be found, I believe that in such an instance it is justifiable to make a clinical, unsubstantiated diagnosis and operate accordingly.

In discussing the treatment of this condition I have in mind the cervico-facial, cellulitis type of lesion, chiefly because this form lends itself to surgical treatment. The actinomycete is strictly anaërobic and not vigorously pathogenic, and if a single granuloma is given a thorough communication with the air, I believe it will be destroyed by this procedure alone. It is next to impossible to locate these areas in the large masses of indurated tissue, and, unlike collections of pus that lie in fascial spaces with normal cleavage planes leading to them, the actinomycotic granuloma is in a solid mass. The only certain method of eradicating it is the radical excision of the entire involved area in one or more stages. I have always made this excision with a knife, but I believe the next one I have to do I will try the high frequency knife to obviate the bleeding. The area to be excised should be marked out in the neck and the incision so planned to avoid, if possible, the branches of the facial nerve. The wound should be funnel-shaped to an exaggerated degree. The bleeding can be best controlled by packing, as one goes along, with absorbent cotton. If the indurated tissue extends behind the mandible this too should be excised. It is better to get beyond the tumor in one part and leave the remainder for later stages, than to do the entire operation in a perfunctory manner. After the excision, if the bleeding is severe, packing with dry cotton for a short time will usually control it. After the excision has been made I have packed the wound with equal parts of Lugol's solution and glycerin. This packing should be changed every other day. If the wound has been properly made and there are no undercuts nor crypts, this packing will come out quite easily and without pain, but the process of inserting the iodin packing is frightfully painful. The pain can be avoided by first packing the wound lightly with cotton soaked in 5 per cent cocain solution. This should be left in for five to ten minutes. The wound can then be packed with iodin gauze. (I use cocain this way very often in doing painful dressings and exploring fresh traumatic wounds and have never seen any constitutional effects from it, although I would hesitate to use the same solution on mucous surfaces.)

If in a week or ten days after such an operation, a portion of the wound has failed to show a sufficient degree of resolution, radical excision should be performed.

I am not sure that potassium iodid given internally has any value. We have given it in increasing doses to all our patients, but favorable results followed only in conjunction with surgical procedures.

We have tried *x*-ray and radium, but I will admit that the cases in which we tried them were not fair tests of the treatment.

REPORT OF CASES

Case. 1—Mr. A. K., a rancher, thirty-two years of age, entered the Miller Hospital on January 26, 1929, with complaint of a discharging sinus in the left side of the neck and jaw. The present illness had begun five months previous to hospital entrance, when the patient got a foxtail grass under his tongue. About ten days later a small lump appeared in the left side of his jaw. At the end of three weeks it was lanced, only a very small amount of pus being obtained. The wound was packed with iodoform gauze until it closed. It again increased in size and six weeks later was reopened. It healed the second time. The induration increased and shortly before admission to the hospital it broke down and discharged of its own accord.

Past history was negative and the family history was not pertinent to the patient's condition. Social history brought out the fact that he had looked after stock all his life, but there was no history of actinomycosis in his cattle in recent years.

Physical examination was negative except for chronically infected and hypertrophied tonsils and the essential pathology, which was a mass on the left side of his neck extending from the parotid region to the midline and filling the anterior cervical triangle. There was an opening in the most prominent part of the tumor, which exuded considerable pus, and scars from previous operations were evident.

The blood and urine were normal.

The day after admission a complete excision of the mass in the anterior cervical triangle was made under ether anesthesia. The wound was packed with gauze soaked in 50 per cent Lugol's solution and glycerin. This was changed frequently, the wound first being cocainized before insertion of the iodin gauze.

Twenty days after operation the wound had almost healed, and a tonsillectomy was performed under local anesthesia, without complications.

Patient was discharged thirty days after admission and has been subsequently reported as well.

Case 2.—Mr. R. R., railroad executive, forty-two years of age.

The patient rode horseback but had nothing to do with the care of animals nor with cattle. Three months before admission, while driving in the country, he stopped at a farm house and while walking through a lane picked an ear of grain and held it in his mouth. One of the barbs from the grain stuck in the posterior part of his tongue. He made several futile attempts to remove it and was still conscious of its presence the next morning, when he consulted a nose and throat specialist, who was unable to remove the foreign body. When I saw him, approximately three months later, he had a tumor of the tongue just anterior to the lingual tonsil. Incision was made into it and with a curette some soft, red, friable tissue was removed. There was one small mass of pus which contained a typical sulphur granule in which the ray-fungus was identified. The incision over the mass was enlarged so that the wound was as large as the widest part of the granuloma. It was packed with gauze soaked in Lugol's solution and glycerin every day until it entirely healed. At the end of two weeks it had entirely healed and there has been no recurrence.

Case 3.—Miss F. K., a clerk, twenty-seven years of age, was admitted to the Miller Hospital on June 27, 1922, with a complaint of soreness and stiffness of the tongue and difficulty with speech. Present illness began five months previous to hospital entrance, when she noted that her tongue felt stiff and sore and ached a great deal. These symptoms would be aggravated by attacks of tonsillitis. Shortly before admission a tonsillectomy was done, but with only slight improvement. One week before entering the hospital a small, dark red spot resembling a blood blister appeared near the midline of the dorsum of the tongue about one inch from the tip. This spot persisted. She also complained of headache, nausea and frequent colds.

The family and social histories were essentially negative. Past history was negative except for frequent attacks of quinsy and sore throats since she was twelve years old.

Physical examination showed on the dorsum of the tongue a small fistulous opening directly in the midline, about which there was some induration resembling a cylindrical mass extending from the dorsum of the tongue to the region of the hyoid bone.

Under local anesthesia an elliptical incision was made on the dorsum of the tongue around the fistulous opening and the cavity exposed would admit a finger. This was filled with dark red granulations. It extended as far as the hyoid bone, apparently in the substance of the hyoglossus muscles. The cavity was thoroughly curetted and packed with iodin gauze.

The microscopic examination showed the curettings to consist of fibroblasts, lymphocytes and pus cells. There was one small round body surrounded by pus cells consisting of a mass of coiled, blue-stained filaments surrounded by a corona of radiating, red-stained clubs typical of the ray-fungus.

The patient was discharged as cured in four months and there has been no recurrence.

Case 4.—Mr. B. F. R., a live-stock commission merchant, thirty-five years of age, entered the hospital, complaining of a mass on the right side of the neck, stiffness in the neck and some pain.

Patient was a live-stock commission merchant at South Saint Paul and his work necessitated his being around stock and he was given to chewing hay. About one month previous to his admission a small mass appeared near the angle of the jaw. This gradually increased in size until it reached anteriorly almost to the midline. The patient's own diagnosis was that he had "lump jaw" and that it was caused by his habit of chewing hay. His past history was negative.

Physical examination was negative except for a firm, hard, slightly tender mass on the right side of the neck extending from the angle of the jaw toward the midline. Near the center of this mass was a small point of fluctuation.

At operation the mass was opened and a granulomatous cavity about the size of a hickory nut was found. Material from this mass showed the typical sulphur granule. The entire indurated area was then excised and packed with iodin gauze. The excised tissue showed one or two other granulomatous areas.

The wound healed entirely and his recovery was uneventful.

Case No. 5—Mr. O. M., a farmer, sixty-five years of age, entered the hospital on September 22, 1928, with a diagnosis of advanced actinomycosis in the cervico-facial region.

About three months previous to admission there was induration in the left submaxillary region. One month previous to admission patient developed pain and some dysphagia. His lower jaw began to swell, was hard and lumpy and very painful. This region was opened several times during the month before admission, but the process continued to extend.

In taking the family history it was learned that he had a son who died of a peculiar pneumonia that was preceded by a chronic abscess in the region of his jaw.

Physical examination showed an old man in fair health except for a hard, ulcerating, tender mass involving the entire parotid region and entire anterior angle of the neck. When pressure was exerted in the neighborhood of one of the fistulous tracts some pus with one sulphur granule was expressed. This was the only one we ever found.

The patient was operated on the day after admission and a fairly radical excision of the entire mass was made. The wound was packed with iodin-glycerin gauze. Two weeks later there was still a great deal of induration at the base of the wound and toward the angle of the jaw. A second operation was done, the excision being carried to the mandible, which was laid bare on its inferior and mesial aspects and the tissues excised toward the floor of the mouth. It was again packed with iodin gauze and hot, wet dressings were applied. This treatment was continued for a period of about thirty days, when he was allowed to go home under the same treatment.

A report from his family doctor indicated a gradual improvement and six months later his wound was entirely healed. Another six months showed no recurrence.

CONCLUSION

Actinomycosis is not rare. The fact that it is an anaërobic infection suggests its treatment. The sulphur granules are not numerous and may not be found. If this is the case, and the clinical picture is typical, the condition should be treated as though it were actinomycosis. The treatment should be radical excision and, if necessary, multiple operations until resolution of the induration is certain. Local treatment of the wound with iodin is probably of value. Frequent dressings with repacking of the wound is necessary to provide an unfavorable anaërobic situation.

DISCUSSION

Dr. James F. Percy (Los Angeles, Calif.): I would like to say a word in reference to the treatment of this condition. Dr. Zimmermann spoke of the high frequency on cures. If he will use the cautery he will not only clear up the cases very quickly, but he will have no pain and no hemorrhage. The high frequency will leave a sore or a surface that does not heal well, and it has practically no effect on the fungus growth.

I have a rule that can be followed in these infections, just as I followed it in cancer, in using the cautery: All tissues normally movable fixed by the pathology make normally movable again with the heat. This rule applied in this situation will clear up these cases very quickly.

Dr. W. M. Mills (Topeka, Kans.): I would like to ask if the Doctor places any value on the sustoxin treatment, or the iodid treatment.

In connection with Dr. Percy's statement, I had one case of actinomycosis of the palate, which was treated extensively by radium, with no results whatever. So I used a cautery and got prompt results. The infection was entirely healed in three weeks.

Dr. W. B. Holden (Portland, Ore.): I was wondering if anyone had used thymol in the treatment of actinomycosis, as brought out by Dr. Myers, at the University of Oregon. He has published somewhere—I can't tell you where—some very remarkable results in the use of thymol internally and locally in the treatment of actinomycosis.

Dr. A. L. Blesh (Oklahoma City, Okla.): I will say that my first experience with actinomycosis occurred when I was a boy on the farm, in the disease known as "lumpy jaw" in cattle. The cautery was extensively used in those cases by the farmers themselves and veterinaries, without curing the cases as they occurred in the animals.

My own experience in the treatment of actinomycosis has not been extremely satisfactory. I have treated most of my cases with iodin in some form or other.

One particular case I recall I had a great deal of trouble with. I sent the patient to Rochester, and they sent him back without operating. So I really am gratified to know that Dr. Zimmermann has been sucessful and I shall try to take some lesson home with me on that score. I observe, in his discussion of the treatment, that in some of the cases he has merely corrected the condition, and then packed it with Lugol's solution. I wonder if he reached all the germs or all the infection by his operation or whether in this instance he intended the solution to cure the condition. I would like to have him bring that out.

Dr. F. E. Clough (San Bernardino, Calif.): I would like to ask one question relative to the use of copper sulphate internally and externally: Is it extensively used?

Dr. Rowland H. Harris (Battle Creek, Mich.): I want to report two cases of actinomycosis that I have had: One was the case of actinomycosis of the tongue, occurring at the tip of the tongue, a mass about the size of a hickory nut. I made a clean incision and suture of the tongue and cleared out the granuloma under the jaw. The man is still alive, after five years, with no signs of any recurrence. I did nothing but the excision.

The other case is a woman upon whom I operated about twelve years ago for the removal of her appendix. I did not get the diagnosis then of actinomycosis. Several years later I operated again and removed the right ovary. I removed a mass the size of a goose egg that was actinomycosis. Two or three years later she developed actinomycosis on the left side, probably from some left over from the right side, and an abscess formed in the groin. She was given large doses of potassium iodid. She is still alive and quite well.

Dr. Gatewood (Chicago, Ill.): I left two cases of actinomycosis when I left Chicago, and I expect a third one when I get back. One of them was a gas case; one was an ileocecal type, either involving the subphrenic region or the abdominal wall.

A word about diagnosis. Dr. Zimmermann has brought out the fact that the clinical picture is characteristic. It is so characteristic that one can make a diagnosis in spite of the laboratory findings. The best laboratory method we have found is biopsy. When repeated microscopic sections and cultures fail, biopsy of some of the granulated tissue will show the fungus in the tissue.

In regard to the use of copper sulphate, Dr. Zimmermann will answer that from his experience, but I can say a few words about it from our experience. The injection of copper sulphate makes a great many people sick, and I have been very doubtful as to its effect. I think potassium iodid possibly does more good internally, in the way of local application. Whether it is of benefit or not depends upon the kind of glasses the man wears: If they are blue, it cures them; if they are plain, it doesn't.

There is one other thing in the way of treatment that has not been mentioned, which I cannot pass by, because Monterey has the credit of curing at least one case: A patient who had been operated upon a number of times went from 160 pounds down to 90 pounds, and was given up as a hopeless proposition, the lesions being too extensive for a radical operation. That patient came here to Monterey and, living out-of-doors with nothing on, returned to Wisconsin at the end of two years' time, having regained her normal weight, without any other treatment.

Dr. Zimmermann (closing): With regard to the general treatment: We have used potassium iodid in all of our cases, but have not had favorable results. We have one Chinese patient with pulmonary actinomycosis who has had it for a year, and he has been spitting up sulphur granules and a great deal of pus. He had everything, but I blame the potassium iodid. He apparently is slightly improved but he still has x-ray evidences of a rather extensive lesion. He is not spitting any more of the granules and his sputum is a little bit less. I am sure that he will die of actinomycosis, although apparently he is somewhat improved.

With regard to thymol: I haven't tried it, but the reports do not look very convincing. Copper sulphate was tried some years ago; my partner tried it in one or two cases and got no results. Also, the literature on that was not very convincing.

I feel about actinomycosis as I do about cancer—nothing can be done by surgery that is half as bad as what they will do themselves eventually.

A wide incision, leaving the wound widely open, dressing frequently, and keeping it exposed is, I think, the crux of the treatment.

In regard to the suggestion that the cautery might cure actinomycosis because it has been tried on animals: I had an interesting experience in trying to work out the bacteriology of this thing. I sent to the stockyards for actinomycotic jaws of cattle. I got several specimens that were condemned as being actinomycotic. None were. They were specimens of lymphadenitis in the region of the jaw. I think the farmers who are around cattle are inclined to call any lump about the jaw actinomycosis. Lymphadenitis does occur in cattle.

Of course, with regard to the dissection of lymph nodes—it is not a question of lymph node dissection, it is a question of a wide excision of a large iflammatory area. The actinomycosis does not extend to the lymph channels, but it grows in the tissues and makes these granulomatous areas.

CASE REPORTS

BILATERAL SPONTANEOUS PNEUMOTHORAX

REPORT OF CASE

John G. Lamont, M.D.
Nopeming, Minnesota

This condition has been described as a fatal complication in pulmonary tuberculosis by Meyer, Marshak, E. A. Gray, Bourne, Greshey, LeWald, Elte, Benedict and Donahue.

Emmerson and Boeler and also Benedict report the complication as a cause of death in asthma. Briggs cites a similar result in a metal worker in whom autopsy revealed gastric carcinoma without evident metastasis to lung tissue.

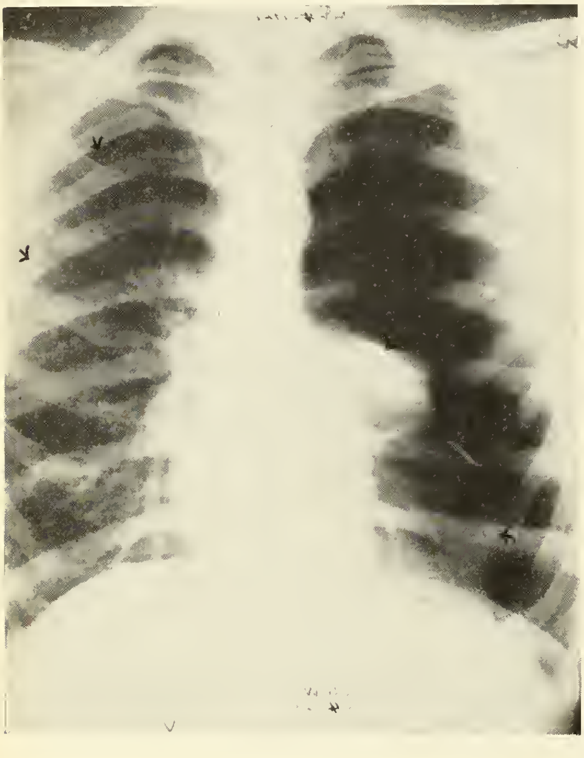

Fig. 1. October 4 (day following collapse). Lung margins right and left are indicated by arrows. Left upper lobe forms a dense shadow close to mediastinum.

Recovery has been reported in only five cases, exclusive of the present instance. Hawes, Jr., Gershey and Hazen each cite recovery from the complication in pulmonary tuberculosis, Eberts in a bilateral pyopneumothorax, and Bedford and Joules a complete recovery after fourteen days, in a patient otherwise healthy. In all patients who have recovered, some form of pleural deflation was used.

CASE REPORT

On October 3, 1927, W. L., a young North Dakota farmer, was employed in pumping water with a double-cylinder hand-pump, into a water tank used to supply a steam threshing engine. Each tank filling involved a half hour of hurried labor. When the tank was almost filled, he was seized with pain in the left side of the chest, severe dyspnea and faintness. He reclined upon the top of the tank, and shortly, finding breathing less difficult, reached for the reins, and while still lying down, succeeded in driving his team and tank to the machines about a quarter mile.

He was carried into the farm house, and received medical attention from Dr. F. K. Kolb of Granville, North Dakota, who conveyed him next day by auto to the North Dakota Tuberculosis Sanatorium, a distance of seventy miles.

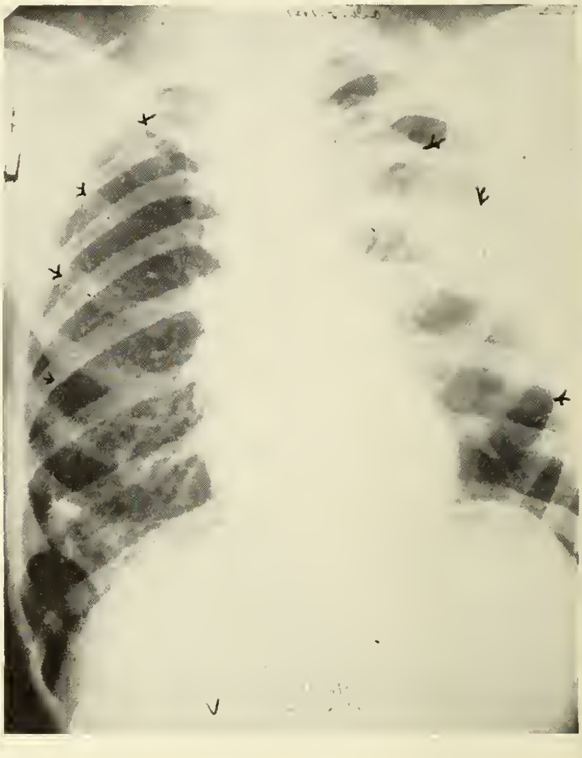

Fig. 2. October 5. Second day. Skiagram following aspiration of 1,500 c.c. of air from left pleura. Left lung is partially expanded; heart and mediastinum drawn to left of former position; apparent increase in right pneumothorax.

The first plate (Fig. 1), taken upon admission, indicated almost complete collapse of left lung, and a well defined air-space on the right side. The left upper lobe formed a dense mass close to the mediastinum, and moved freely with the cardiac impulse. There was moderate cyanosis, and rather profuse perspiration. Pulse 98, respiration 36, mouth temperature 98°.

Family History.—Father and mother are living, other members of family healthy. There is no history of tuberculosis contact.

Personal History.—He had always been well, except for occasional gastric disturbance, and had always lived and worked with his father on the farm. He had had no infectious diseases of childhood.

Examination.—The patient is a white male, well nourished and weighing 145 pounds.

The entire left side of the chest presents a hypertympany with absence of respiratory sounds and a

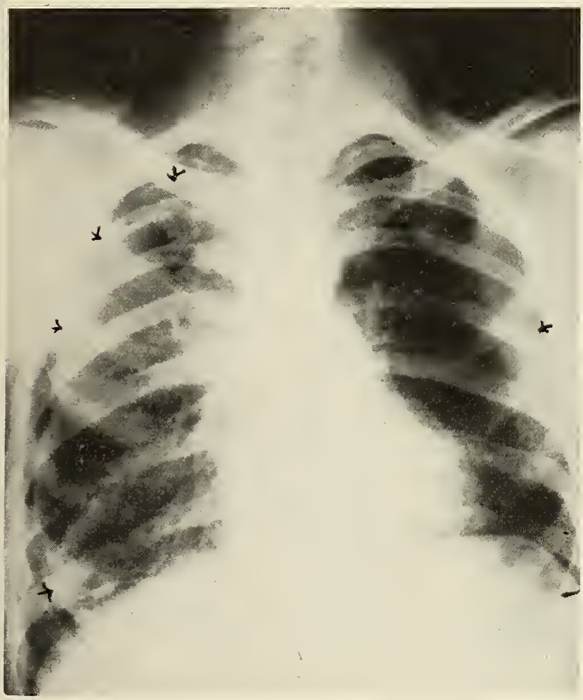

Fig. 3. October 10. Left lung is more fully expanded; heart in better position; right air-space smaller; atelectatic areas in right lung field.

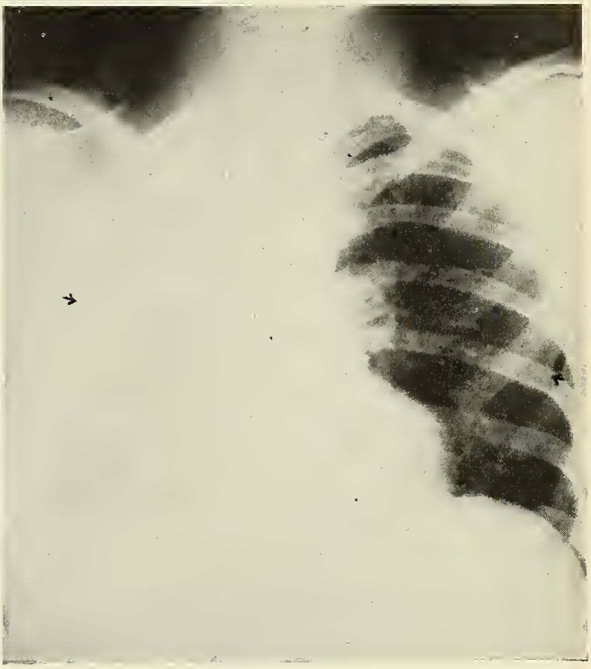

Fig. 4. November 25. Left lung is expanded; right lung field and air-space more completely obscured.

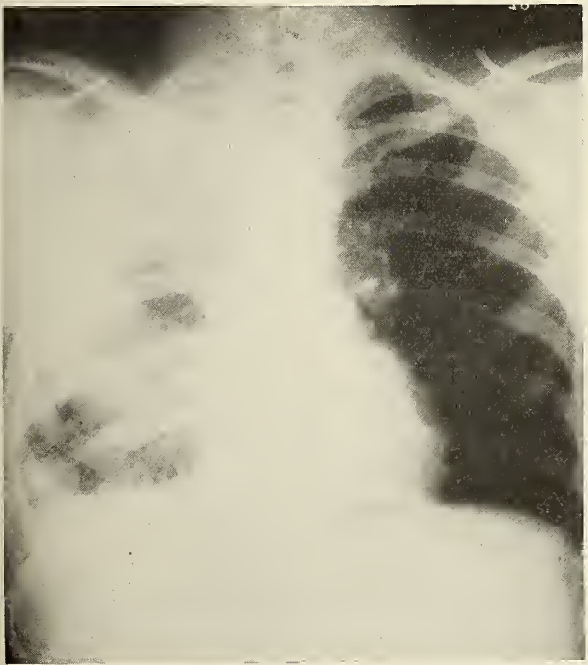

Fig. 5. December 29. Partial clearing of right lung field. There is complete expansion of left lung; small air-space in right costal angle.

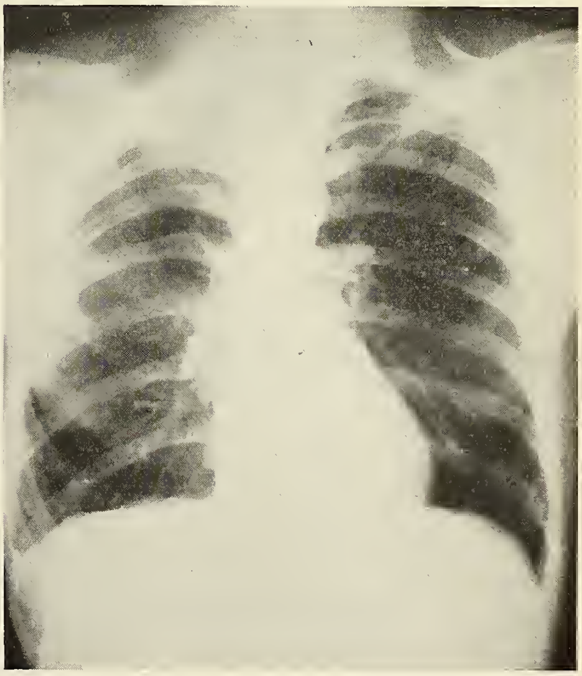

Fig. 6. September 21, 1930. Three years following attack. There is diffuse fibrosis in right upper lobe and left apex.

definite bulging of the chest wall. The respiratory murmur on right side is distant, except posteriorly. No râles are heard.

Course.—October 5, 1927, the left pleural space was aspirated in the eighth interspace, with an ordinary pneumothorax needle, and vacuum bottle. After 1,500 c.c. of air had been withdrawn, the operation was discontinued, because of a spasm of coughing. There was prompt relief from dyspnea, and Plate II was made within an hour, which indicated moderate expansion of the left lung, improved heart position, and slight increase in the right pneumothorax.

For several days, the patient was fairly comfortable, and no further deflation was attempted. The temperature ranged, however to 101.8 and pulse 96, and October 10th a skiagram (Fig. 3) showed clouding of the right lung field, with areas of atelectasis. The left lung maintained good expansion. There was no apparent increase in the pneumothorax on the right side.

Until October 22, the daily temperature ranged 100 to 102.8 with much restlessness, relieved by opium.

Severe dyspnea recurred suddenly on the morning of October 22nd. Aspiration of 1,500 c.c. at 3:30 p. m. from the left side gave much relief. The temperature fell during this day below normal, and, except for a slight evening rise, continued so, during later convalescence. On October 23, 900 c.c. and 1,000 c.c. were again removed. Gradual improvement continued during November and December. On November 25, the patient was able to visit the *x*-ray room. The *x*-ray indicated dense clouding of entire right lung field (Fig. 4). This showed moderate clearing on December 29 (Fig. 5).

Patient was allowed to leave the sanatorium on January 6, 1928, in good physical condition. The sputum, always scant, was repeatedly negative for tubercle bacilli. Von Pirquet skin reaction was positive. Following a report from Dr. Kolb in September, 1930, that the patient was doing ordinary farm work, at home, a request was made for a skiagram. The view shown in Figure 6 was taken September 21, 1930, and indicates only a moderate degree of diffuse fibrosis in the right lung, and left upper lobe. Patient states that he feels entirely well.

Comment.—Bilateral spontaneous pneumothorax may occur in apparently healthy individuals, following unusual exertion. It is commonly a complication of tuberculosis, or other conditions resulting in localized emphysema, with accompanying attenuation of the adjacent pleura. No parenchymal lesion due to tuberculosis was evident in the case above described. It is improbable that air passes from one pleural space to the other, as the unilateral form rarely becomes extrapleural under positive tension.

Deflation by use of the reversed pneumothorax apparatus is of value, in selected cases.

Acknowledgment is made of the use of the *x*-ray files and records of the North Dakota Tuberculosis Sanatorium at San Haven, N. D.

SUBACUTE BACTERIAL ENDOCARDITIS INVOLVING THE TRICUSPID VALVE ONLY*

REPORT OF CASE

HARRY OERTING, M.D.
Saint Paul

The case I present this morning is that of an adult white male, aged 46, who was admitted to my service at the Ancker Hospital, St. Paul, on October 27, 1929, complaining of fever, chills, cough, vomiting and pain in the chest of three weeks duration. The onset, October 6, 1929, was extremely sudden and violent, with chills and a high fever. He was very ill for two or three days and since that time he felt only fairly well, and the cough and pain in the chest did not improve very much. Three days before admission he began to have nausea and vomiting.

The past history is negative except that he has always been subject to frequent colds and has had pneumonia several times.

The positive physical findings on admission were dental caries, marked pharyngeal injection, mild cervical adenopathy, dullness over both lower lobes of the lungs, the left more than the right. The breath sounds were harsh, with many râles over the right side posteriorly. There was bronchial breathing over the left lower lobe. There was a friction rub over both lower lobes posteriorly. The heart was moderately enlarged, rate 120, and the tone quality was rather poor, but otherwise there seemed to be no abnormality. No murmurs or bruits were heard. The abdomen and extremities were negative. The temperature was 100 F. and the blood pressure 115/90. The tentative diagnosis on admission was bronchopneumonia, pleurisy with effusion and a questionable empyema.

The laboratory data follow: Urine 1.020; albumin a faint trace with occasional hyaline and granular casts and a few blood cells. Stool negative. Wassermann positive. Blood chemistry: creatinine 2.8 mg.; urea N.

---

*Presented before the Minnesota Society of Internal Medicine, Duluth, Minn., May 26, 1930.

160.3 mg. Blood: Hgb. 59%, r.b.c. 3,190,000, w.b.c. 12,000. *X*-ray: Heart definitely enlarged, 6.5/11.3, comprising 58% of the chest diameter. Lungs: Infiltration at both bases which may be inflammatory but is probably due to congestion. There is a thickened interlobar pleura on the right between the middle and lower lobes. Possibly a resolving pneumonia. Sputum negative for Tbc. On October 31st thoracentesis was done and 40 c.c. of a clear straw colored fluid was removed which showed nothing microscopically.

The general condition remained about the same and daily observations failed to reveal any heart murmurs. On October 31st the patient became irrational, the temperature rose to 101, the white blood count was 17,800. The physical findings were not unlike those on admission. The spleen and liver were not palpable and no petechial spots were present. The condition remained about the same until November 4, 1929, when there was a sudden change. The breathing became very labored, the pulse very weak, the liver was definitely palpable, the spleen was not felt, the lungs showed a diffuse patchy tubular type of breathing over both lungs posteriorly. Numerous petechial spots appeared over the back, chest and extremities. The heart tones were rough and slurred but there was no murmur. At this time a diagnosis of subacute bacterial endocarditis was made with no definite idea of which valve was involved; bronchopneumonia; left pleural effusion; congestive heart failure.

On the afternoon of November 4 the patient died and the following are the essential autopsy findings:

Pericardium normal.

Heart.—Weight 400 grams. Mitral and pulmonary leaflets are normal in appearance. The aortic leaflets are sealed together at the commissure but there is no evidence of an acute vegetative lesion. The tricuspid leaflet shows a large thrombotic vegetation which measures about 3 × 1.5 cms. This is situated on the posterior tricuspid leaflet. It is soft and friable. Scattered over the balance of the valve there is a rather diffuse vegetative lesion which is flat and fairly firm. This does not resemble the small nodular type of lesion seen in pneumonic endocarditis. There is no evidence of luetic aortitis. The coronaries are normal. There is no gross evidence of excess fat or fibrosis. The myocardium is flabby and after cutting is found to be pale and swollen in appearance.

Pleural Cavities.—The left pleural cavity contains about 500 c.c. of clear straw colored fluid.

Lungs.—Consolidation along the posterior border of the right lung. Scattered throughout the lung are numerous nodules with a firm consistency and situated beneath the pleura. On cutting, these nodules are yellowish in color and well defined from the balance of the lung tissue. The left lung shows consolidation involving the lower portion of the upper lobe and the posterior portion of the lower lobe.

Spleen: The spleen weighs 94 grams. There are several well defined areas of infarction.

Kidneys.—There is no evidence of infarction.

Post-mortem Diagnosis. Subacute bacterial endocarditis (tricuspid). Multiple infarcts of the right lung and spleen. Bronchopneumonia, bilateral. Splenomegaly. Meckel's diverticulum. Pleural effusion (left).

DOCTORS' BILLS

It is perhaps not strange that the medical profession in Minnesota is not greatly impressed with the cry that is heard so frequently about high doctors' bills. The fee schedule varies greatly and in Minnesota is very moderate compared to that in the large eastern cities.

Are doctors' fees so exorbitant? Compare them with those of an attorney in the same community. Or, compare the sum total with the sum spent for tobacco, cosmetics, radios, automobiles —all of them less important commodities.

The main difference, however, in medical expense compared with other expense, is that no provision is made in the family budget for medical expense, and the total cost to the nation is not evenly distributed. Inquiry would show that there are few individual accounts that run over $300 a year. A fee of this amount, however, would represent only a portion of the total cost of any particular illness. It must be admitted that in an appreciable, though small, percentage of instances, the financial burden due to serious or protracted illness is a heavy burden.

An article by the Director of the Twentieth Century Fund* offers food for thought. The author praises the scientific attainment of the profession but deplores its lack of organization in rendering medical service. He sees great opportunities for economizing in group practice. We doubt whether the existing medical groups can show any marked reduction in medical costs to their patients. Medical fees in any locality are much the same whether services are rendered by physicians as individuals or in groups. The author is keenly interested in the insurance plan. We have been and are. The author's recommendation is a combination of group practice and insurance by so-called guilds, thus combining the advantages of group practice and medical insurance in one unit. This guild would provide complete medical services to the families of members, including periodic examination for the detection of early disease, hospital and other medical services in case of sickness. It sounds well.

Various objections come to one's mind. There would be many opportunities for abuse of medical service furnished through insurance. The neurotic would be in his (her) glory. This individual would pester the life of the doctor more than at present. Every patient would demand day and night nurses and the most expensive room in the hospital, and minor illnesses might be prolonged inordinately. The individual would have to accept the services of the guild doctor and freedom of choice would not be possible. And, if freedom of choice as to medical attendant were permitted, the unscrupulous doctor could add to his fees. The main objection to the insurance plan for meeting medical costs is that so far it hasn't worked very well. To be a financial success, the rates would have to be rather high—according to the author mentioned, some $200 per working man's family. The average working man would take the chance that sickness or accident would not come to his family or that his bills would not amount to that much in a year and would not take out the insurance.

---

*Clark Evans: A Cure for Doctors' Bills. The Atlantic Monthly, October, 1930.

Sufficient statistics are not as yet available to warrant insurance of this sort. The author cited refers to recent studies carried out by the Metropolitan Life Insurance Company which showed that families of working men spent, on an average, $140 a year for medical care. Two-thirds of the total amount was spent by one-fifth of these families.

Possibly the study being made by the Committee on the Cost of Medical Care, of which Dr. Ray Lyman Wilbur is chairman, will be able to present figures reliable enough to warrant the issuance of policies to cover, if not the total cost to a family, two-thirds or three-quarters of the cost. Such a policy might eliminate most of the objections to insurance as the answer to the high cost of medical care. Such a solution would certainly be welcomed by the medical profession.

THE USE OF TOXOID FOR IMMUNIZATION AGAINST DIPHTHERIA

Since the discovery by Behring in 1913 that active immunization against diphtheria could be produced in susceptible individuals by injecting small amounts of a carefully prepared mixture of toxin-antitoxin, much investigative effort and experimental research has been done to overcome the objectionable features of the procedure. The reactions to the early preparations of toxin-antitoxin were often so severe that it created in the minds of both physicians and laymen, if not a feeling of opposition, at least a feeling of reserve, regarding the routine use of the mixture for diphtheria prevention.

Park and Zingher, in New York City, by using considerably smaller amounts of toxin, were able to prepare a mixture of toxin-antitoxin which practically eliminated the severe reactions associated with the giving of the earlier preparations. In 1924, Zingher[1] reported the immunization of 91 per cent of a large group of susceptible New York school children, as shown by negative Schick tests six months after giving of three doses of 1 c.c. each of .1 L + toxin-antitoxin. No unfavorable reactions occurred incident to its use. Other clinicians have reported very much the same results.

Very largely as a result of the work of Park and Zingher, the use of 0.1 L + toxin-antitoxin for routine active immunization against diphtheria spread over the United States, with a marked reduction in the incidence of diphtheria in those areas where its use was prevalent. Coincident with the increased use of toxin-antitoxin for immunization appeared increasing numbers of reports of the occurrence of severe reactions to later therapeutic administration of horse serum. Due to the presence in the antitoxin component of toxin-antitoxin of small amounts of horse serum, many investigators believed that by the increased use of toxin-antitoxin an increasing number of children were being sensitized to horse serum. Other objections to toxin-antitoxin were the difficulties of preparations of the mixture, the difficulties of preservation of the material, the number of inoculations necessary to produce immunity, and the slowness of immunization, which required from four to six months to develop.

In 1923, while the very excellent work of Park and Zingher in this country was directed toward dilution of the toxin in toxin-antitoxin mixtures in order to overcome the undesirable reactions incident to its use, Ramon,[2] working in the Pasteur Institute and American Hospital at Paris, produced a modification of diphtheria toxin by the addition of a small amount (4 c.c.) of commercial formaldehyde solution to 1,000 c.c. of a standard diphtheria toxin preparation. When this mixture was allowed to stand for one month, at a temperature of 38 to 40 degrees C., it was found to be free of all the toxic properties of diphtheria toxin. At the same time it had the power to produce antitoxin, when injected into the body; the ability to retain these properties over a long period of time without special precautions for its preservation; and, further, the material contained no horse serum. This product was called anatoxin by Ramon. The same material, further modified and improved, is now more generally called toxoid.

---

[1] Zingher, Abraham: Proc. Soc. Exper. Biol. and Med., 22:462, 1924-25.

[2] Ramon, G.: Paris Med., 20:480 (Dec. 6), 1924.

In 1928, Ramon and Helie[3] reported their experiences with toxoid to the physicians in America. Since their report appeared, a series of clinical investigations have been carried on by numerous workers, attempting to determine the relative merits of the antigenic properties of toxin-antitoxin and toxoid.

Recently Harrison,[4] under very carefully controlled clinical conditions, gave 355 Schick-positive children, ranging from one to sixteen years, three doses of 1 c.c. of toxin-antitoxin. Four months later, the Schick test was negative in 64 per cent of the cases. Different lots of stock preparations varied in degree of effectiveness from 35 to 73 per cent. For comparison, toxoid, routinely prepared, was given to another group of 476 Schick-positive children. Some of the group were given three doses of toxoid (.5 c.c., .5 c.c. and 1 c.c.) at seven day intervals; others were given two doses of 1 c.c. each at an interval of thirty-one days. Schick tests about four months later showed production of immunity in 95 per cent of the cases. Twenty-seven children over six years of age were found previous to the giving of toxoid to be sensitive to the diluted toxoid and these children were given toxin-antitoxin. No local or general reactions incident to the use of either toxin-antitoxin or toxoid were reported. The low average percentage of immunity production recorded by Harrison with toxin-antitoxin would probably have been higher had the Schick test been applied six instead of four months later.

From the accumulating evidence, reports indicate that toxoid offers the advantages of smaller dosage, that immunity can be established in a shorter length of time, in a higher percentage of cases, and there is no horse serum in the preparation to produce sensitization. A disadvantage to the use of toxoid is the reaction which may occur in children over six years of age. This may be determined by testing in a manner similar to the Schick test, previous to the giving of the toxoid. In case the individual is susceptible, toxin-antitoxin can be given without unfavorable reaction.

PNEUMOCOCCIC SERUM

The serum treatment of pneumonia has had few enthusiastic supporters since it was first used before the war. The fact that the horse does not respond readily in the formation of antibodies to the various types of pneumococci has necessitated the administration of large doses of the unconcentrated serum and repeated intravenous injections. The serum reactions were so frequent and often so severe that the method has never become generally popular. The writer was not favorably impressed by a limited experience with this form of pneumonia treatment in an army hospital during the war.

Recently, however, reports have appeared in the literature, of series of type one pneumonia treated with a serum refined and concentrated according to Felton's method, showing a mortality reduction of ten per cent or more compared with control series. Serum reactions occurred in only ten to twenty per cent of the cases treated, which is much less than was experienced with the unrefined serum.

If one patient in every ten with pneumonia of type one can be saved by this serum, the method is worth while even though the serum treatment is expensive and costs $100 or more per patient. Even the most ardent advocate of the reduction of the costs of medical care would not think the price too great if it increased his chances of recovery ten per cent. The type one group of pneumonia is the most prevalent one, amounting to approximately a third of pneumococcic cases, and roughly, a third of these patients die.

The mortality from pneumonia and even that from the various types of pneumococcic pneumonia, is so variable in different localities, during various seasons, and in the different kinds of hospitals, that an evaluation of a therapeutic measure of this sort has been difficult.

The evidence now on hand, however, of the value of Felton's serum, merits the earnest attention of the profession.

HISTORY COMMITTEE

In these days of laboratory and machine-made diagnosis and treatment, it is difficult to realize how the generations preceding ours practiced medicine. Diagnosis and treatment were personal and an art. Reading the old works shows as much keen clinical observation. That is often lacking nowadays. Who knows whether our first physician possessed a stethoscope or understood the art of percussion? The clinical thermometer was used in St. Paul for the first time about 1870 and we know who brought it here and have one of that era. Do you realize that the hypodermic syringe was not used in the United States till 1856 and that the use of the clinical thermometer and microscope is not mentioned in the Harvard Medical College catalogue until 1867-1868? A Minnesata physician in a case report published in 1856 stated that a microscopic examination of a tumor of the stomach showed cancer cells. Can you inform your Historical Committee anything more about the use of these instruments in the early days in Minnesota?

OBITUARY

Dr. Frederick A. Dunsmoor

1853-1930

Dr. Frederick A. Dunsmoor, one of Minneapolis' outstanding surgeons for almost a half century, founder of the old Minnesota Hospital College and one of the organizers of the medical college at the University of Minnesota, died December 16, 1930, at his home in Hollywood, California, where he lived for the last five years.

Dr. Dunsmoor, who was 77 years old, was born in the Richfield district of Minneapolis. He attended high school in Minneapolis and the University of Minnesota. In early life he determined to go into the medical profession and at the age of 16 years entered the office of Drs. Goodrich and Kimball to study medicine. Subsequently he went to New York, where he was graduated from the Bellevue University and hospital.

Coming back to Minneapolis, he was in partnership for a time with Dr. H. H. Kimball. In 1877 he began to practise independently. About the same time, he accepted a position as professor of surgery in the St. Paul Medical College, where he taught two years. In 1879 he was county physician for Hennepin County.

Dr. Dunsmoor then accepted the chair of surgery in the medical department of Hamline University, which he held two years, resigning to devote himself to the organization of the Minnesota Hospital College.

He bought the old Winslow hotel on Main Street N. E., Minneapolis, and started the college in cooperation with several other physicians and citizens. Then, in 1884, he founded the first eye, ear and nose clinic in the Twin Cities.

He served as vice president and dean of the college besides being professor of surgery, surgeon to the dispensary and attending surgeon to the hospital. While he was in this position, the institution and the St. Paul Medical College were merged to form the medical college at the University of Minnesota, where he was appointed to the chair of clinical and operative surgery, which he held until 1913.

He had an active part in the development of Asbury Hospital and served as surgeon at different times at St. Mary's, St. Barnabas, Swedish and City hospitals. He was also surgeon at different times for more than a half dozen railroads.

Dr. Dunsmoor made it a custom to spend a short vacation each year in study in the great hospitals, colleges and scientific centers of this country and abroad. His articles on his specialties appeared in leading medical journals and he was recognized for his skill as a surgeon throughout the medical world.

Physicians who have worked with him not only praise his skill as a surgeon but also point out that he was always ready to give his service, whether or not the patient had the money to meet the expense.

He was a member of the Hennepin County Medical Society, the Minnesota State Medical Society, the American Medical Association, the Academy of Surgeons and various other medical and surgical organizations.

Dr. Dunsmoor was a charter member of the Minneapolis Club and the Commercial Club, now the Civic and Commerce Association. He was also a member of the Lafayette Club and the Hennepin Avenue Methodist Church, where he served in official capacities for many years.

In the early '80s Dr. Dunsmoor built a home on Tenth Street that was the show place of the city for many years. After the business district expanded to that locality, he moved to a home at Lake Minnetonka.

He was one of the pioneers in building summer homes in the northern part of the state. About 25 years ago he constructed an immense summer home on an island in Rainy lake, 15 miles east of International Falls. He named the island "Minisenot," which is the Indian word for "Home Island." The home is now the property of Dr. N. H. Scheldrup of Minneapolis, husband of a niece of Dr. Dunsmoor.

Dr. Dunsmoor was greatly interested in the beauty and health resources of that territory and at a hearing before the international joint commission at International Falls in 1925, was the first person to publicly suggest the development of an international park in that region which is now under consideration and which the American Legion and the Canadian Legion have suggested be made a memorial to men of the two countries who gave their lives in the war.

Dr. Dunsmoor moved from Minneapolis because of failing health, but he returned for frequent visits. He visited there last summer, at which time he spent almost two months at his old summer home at Rainy lake. He was then subject to heart attacks, of which his death was the result.

Surviving him are two daughters, Mrs. Homer P.

Clark, St. Paul, and Mrs. Frederick W. McCartney, Denver; a brother, Dr. John Dunsmoor, Los Angeles, and three nieces in Minneapolis, Mrs. A. W. Armatage, Mrs. Horace Lowry and Mrs. N. H. Scheldrup.

Dr. W. H. Hallowell

1853-1930

Dr. William Henry Hallowell, physician in Minneapolis for 47 years, died Sunday, December 14, 1930, at Rosedale Hospital following a heart attack.

Dr. Hallowell, who was 77 years old, was born in Philadelphia. He was a graduate of the United States Naval Academy at Annapolis, and an officer in the navy for two years. At that time he won medals in double sculls and as a member of Navy sculling crews.

He was later graduated from the medical department of the University of Pennsylvania, coming to Minneapolis in 1883.

He was a member of the Hennepin County Medical Society, and, before the medical college at Hamline University was consolidated with the University of Minnesota, was head of the obstetrics department there. He had a large charitable practice among the poor for many years.

Surviving Dr. Hallowell are a son, C. C. Hallowell, manual training instructor in the Minneapolis public schools; a daughter, Mrs. Helen Leach of Bremerton, Wash., and a brother, Dr. Charles E. Hallowell of Philadelphia.

Dr. Andrew E. Anderson

1859-1930

Dr. Andrew E. Anderson, one of the founders of Swedish Hospital, died December 11, 1930, at his home in Minneapolis.

Born in Sweden April 2, 1859, Dr. Anderson had been in the United States for 57 years and a resident of Minneapolis for 33 years. One of four doctors who started the Swedish Hospital, he had been on the staff ever since. He was a member of the Hennepin County, Minnesota State, and American Medical Associations. He was a graduate of the Colorado University school of medicine and started practice in Ironwood, Mich.

Surviving Dr. Anderson are his wife, a daughter, Bessie, Iron Mountain, Mich.; two brothers, Albert Malmgren, Marquette, Mich., and S. Malmgren, Ishpeming, Mich.

Dr. Dwight F. Brooks

1849-1930

Dr. Dwight F. Brooks, Saint Paul, though identified prominently with the lumber industry, retained his medical licensure in Minnesota. Born at Redfield, New York, June 10, 1849, he came to Minnesota when a boy of seven, when his father, also a physician, settled at Beaver, a small village in Winona County, Minnesota. Six years later the family moved to Minneiska, a thriving town in the same county. His father later entered the grain business and tried to dissuade his son from pursuing the study of medicine, but in vain. Dwight Brooks, at the age of eighteen, matriculated at the University of Michigan, later attending the Long Island College hospital, where he received his degree in June, 1876. After practicing at Minneiska for a few years, his father's business enterprises claimed more and more of his time. Lumber came to be allied with the grain business and some fourteen branches of the business were established in Minnesota and North Dakota. When, in 1886, a yard was established in the Midway district in the Twin Cities, Dr. Brooks made his home in Union Park, Saint Paul.

In 1894 an alliance was made between his company and that of Scanlon, Gipson and Company, which later became the Brooks-Scanlon Lumber Company. Lumber activities extended to Oregon, Florida, the Bahama Islands, British Columbia as well as Minnesota.

In September, 1875, Dr. Brooks married Anna E. Keyes of Winona. A brother, Anson S. Brooks of Minneapolis, and three sons, Harry K. Brooks of Bend, Oregon, S. S. Brooks of British Columbia, and Edward Brooks of Minneapolis survive him.

MISCELLANEOUS

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

State of Minnesota *vs.* Olga Stenhoff

On December 2, 1930, the State Board of Medical Examiners revoked the massage license of Olga Stenhoff, formerly residing at 2021 Columbus Avenue, Minneapolis, Minn. The defendant was convicted on her plea to the charge of abortion on the third day of October, 1930, in the District Court of Hennepin County. At that time the defendant was sentenced to serve not to exceed two years in the Women's Reformatory at Shakopee, Minnesota, where she is now imprisoned.

MEDICAL BOARD REVOKES LICENSE OF MINNEAPOLIS PHYSICIAN

On Tuesday, December 2nd, the Minnesota State Board of Medical Examiners revoked the license of Philip Mueller, physician and surgeon, with offices at 109 So. 9th St., Minneapolis. The Board found Mueller guilty of immoral, dishonorable and unprofessional conduct, the particular offense being the habitual indulgence by Dr. Mueller in the use of morphine sulphate.

This is not Mueller's first difficulty with the law. On June 6, 1913, the Supreme Court of Minnesota affirmed Dr. Mueller's conviction of manslaughter in the first degree. Dr. Mueller at the time served two years in the State Penitentiary at Stillwater. Dr. Mueller's conviction followed the death on May 17, 1912, of a married woman on whom an abortion had been performed.

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

Senator Jones and "Medical Socialism"

On December 8, the Chicago Journal of Comerce printed as its leading editorial an interesting comment on the Jones bill which its author wishes to bring to a vote in this session of the United States Senate. The editorial printed there in full was called "Medical Socialism." It is one of several editorials on medical matters that have appeared of late in the Journal.

"Senator Jones of Washington is seeking a vote on his bill for an annual appropriation of $1,000,000 to provide medical treatments for mothers and children," says this editorial. "Legislation of this kind has been enacted before but its life has been limited to a term of years. Always it has been argued that the assistance of the federal government in these enterprises was only a transient necessity. But Senator Jones would make it permanent. The federal government is permanently to join with the states in supporting doctors who provide medical treatment for expectant mothers, nursing mothers, mothers past the nursing stage, young babies, older babies and children as old as seven or eight years. Naturally, the $1,000,000 appropriation will increase and the medical activity of Uncle Sam will be expanded. The medical socialist bill of Senator Jones is part of the general socialist movement which is engulfing the United States."

The dark view of things taken by the *Chicago Journal* is not wholly shared by physicians themselves. They know better than any, perhaps, what is the real state of mind of their patients and what reaction is to be expected from them if the state medicine bugaboo should become a universal fact.

"Our patients do not want us to abdicate our position of trust, confidence and independence to become government employes," Robert M. Burns, of St. Paul, declared to members of the Red River Valley Medical Society at Crookston recently. "They would rather, far rather, bear the hardships of private medical costs than accept state medicine.

"While we have gained much knowledge from foreign countries we cannot accept their system of practice. It would be a misfit here, a fatal departure from American traditions. Our constitution guarantees.to all the blessings of liberty."

Dr. Burns also pointed out that state medicine has very little to offer that will solve the difficult problem of the costs of medical care.

"We have full respect for those of our profession who are already doing work that might be considered a sample of state medicine. They have chosen their line of work for one reason or another, according to their adaptability. It is largely a matter of administration and enforcement. They are an essential group to the medical profession but their work is entirely different from the private practice of medicine. It is unthinkable as well as undesirable that we should all follow their example."

PRESIDENT'S LETTER

THERE was a time within the memory of all of us when physicians banded themselves together only for the advancement of science. Their officers were invariably men of conspicuous scientific achievement.

Last July, the Minnesota State Medical Association occupied itself during several important sessions of the sixty-second annual meeting with such unprecedented matters as state and national legislation affecting the profession, economics, veterans' relief, cost of medical care and the public relations of the physician. At that session the state association also elected a country doctor for its president.

I find these very interesting and important commentaries on modern medical practise. That is partly, perhaps, because I happen to be the country doctor chosen. Partly it is because they demonstrate the evolution from purely scientific medicine to social medicine which has come about in America in the last twenty years.

This striking evolution is going on in all of the learned professions but in none so conspicuously as in medicine. It is the inevitable sequel to the striking economic and social shifts of the times.

The doctor has discovered of late that it is not enough to write learned papers to read to his confreres or to distinguish himself in his practise. He has been obliged to form an offensive-defensive alliance with his confreres for his protection as well as the protection of the public. He must battle against the cultist and the fake healer, invested as these latter are with all of the power and glory of modern high power advertising. Upon him, he has found, rests the burden of solution of those baffling problems involved in the high costs of medical care, problems that are inextricably tangled up with all of the economic anomalies and perplexities of modern American life. He must forthwith fortify himself and his profession against the socialistic and bureaucratic tendencies of the times, lest the freedom and integrity and essential ideals of medicine be lost.

It goes without saying that the representatives of this new phase of organized medicine must be men of wide contacts and practical knowledge of organization. It is no longer incompatible with the dignity of the profession and of its glorious traditions that the man chosen to head it during 1931 should not be its most illustrious physician.

For myself, however, I can think of no adequate reason why the great state organization of physicians in Minnesota should have chosen me for the job of president in 1931. I cannot promise to follow with any distinction in the footsteps of my predecessors. I cannot promise more than to conduct myself and the business of this organization as worthily and honestly and energetically as I am able.

But I have had, as it happens, a considerable experience unofficially, with Minnesota politics and Minnesota legislators, and I can promise, knowing the men who have consented to serve on the Legislative Committee of the State Association, that the vitally important legislative program of our organization will be carried on effectively this year.

In fact, I ask every member of the Association to read over the membership of all our committees. It should inspire confidence in the whole association to note again the high type and quality of men willing to work for the good of the medical profession.

Fortified by this confidence, I start now upon one of the most important years and undertakings of my life. I pledge my fellow members of the Minnesota State Medical Association who have placed their trust in me, the utmost of my abilities and energies and strength in their behalf.

L. Sogge

President
Minnesota State Medical Association.

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I have a patient with a definite pernicious anemia who has been on liver treatment for some three years or more. The blood picture is staying up well but for the past four or five months the patient has had a lot of trouble walking. She falls and stumbles very easily, and now cannot walk at all without help. I am wondering if anyone has reported any cases of pernicious anemia where the blood picture has remained practically normal on liver therapy and yet there has been a gradual increase in the cord symptoms. Is there any special type of treatment that will help diseased cord symptoms? She apparently needs no treatment as far as the blood goes.

   Answer.—Early reports regarding improvement in involvement of the nervous system were pessimistic, but more recently they have been more encouraging. There have been several reports which indicated that the patient developed cord changes after the blood had returned to normal. B. M. Baker, Jr., Bordley, J. B., III, and Longcope, W. T., MINNESOTA MEDICINE, XIII:815, (Nov.), 1930, report forty-four cases of pernicious anemia in which there were symptoms referable to change in the central nervous system who have been treated by liver or a combination of liver and liver extract. Of twenty-three cases followed for more than six months, improvement in symptoms and signs occurred in 55.17 per cent. In twenty-one cases treated less than six months improvement was noticed in only 31.25 per cent. In eight cases of outspoken subacute combined degeneration, treated for more than tei months, there was improvement in symptoms and signs in 58.9 per cent. They state that it is essential that large quantities of liver, or liver and liver extract, be employed over long periods of time. They recommend 400 grams of liver or more daily or its equivalent. No results need be expected in less than six to eight months. The longer the patient continues the treatments, the less liable it is for remission to occur.

2. *Question.*—A primipara has engaged me to confine her later on this month. Her urine looked bloody on examination and I found it loaded with albumin. I had her wash off the parts thoroughly before collecting the same so as to avoid contamination. Can you outline a course of treatment? What is the prognosis for mother and baby?

   Answer.—The dark colored urine is either due to blood or concentration. It would be advisable to do a microscopic examination of the sediment before deciding which was the cause. Albuminuria in a pregnant woman may mean toxemia of pregnancy. It is advisable to make blood pressure examinations although toxemia might be present without elevation of the blood pressure. Usually edema can be found. Non-renal causes of albuminuria are cystitis, pyelitis and contamination from the external genitalia. While looking for red blood cells, it would also be advisable to look for pus cells. If you make a diagnosis of toxemia of pregnancy, the patient should be put to bed, the intake and output watched, and a restricted protein diet given. It is also advisable to increase the carbohydrate in the diet and to make frequent observations of the blood pressure. The fetus may be dead at this time. The prognosis for the mother in toxemia pregnancy is usually good but not so good for the fetus. You had better examine the urine and if only albumin and casts are present, treat the patient as a potential toxemia case.

3. *Question.*—A married man, while working with a thresher got a barley beard in the lower lid of his left eye. The beard pierced the lid. The eye pained him so intensely that he was taken in for examination and treatment. He arrived two hours after the accident. A portion of a barley beard was removed. The pain was so great, however, through the night that he returned for a second examination and treatment, and more of the beard was found and taken out. He did not obtain relief. The following day the pain was more severe and examination revealed an acute left frontal sinusitis. What is the etiology of the frontal sinusitis? Could this be secondary to an infection in the eye? If so, by what route? Was it through the duct up the nose? Through the lymphatics or through the blood stream? Is the sinus infection entirely incidental?

   Answer.—It is possible for a conjunctivitis to invade the sac of the lacrymal duct and go up through the nose to the frontal sinus. This is rather remote, however, and the acute frontal sinusitis is probably an incidental affair. If it did occur, it would probably be through the duct and not through the blood stream or lymphatics.

4. *Question.*—A nine year old girl turned her right ankle. X-ray the next day showed the fibular epiphysis a trifle wider than the tibial and the toes swung in. I put it up straight. There has been no pain and she can extend the foot and swing it to both sides. The swelling is almost gone (26 days) and almost no tenderness can be elicited on manipulation. But ecchymosis is still present and apparently not fading below the tibia. Except for this, I would think that everything was fine, but fear non-union on account of the delay in absorption of the blood.

   Answer.—Your patient apparently had an epiphyseal separation and was well treated. The almost complete disappearance of swelling, absence of tenderness on massage and manipulation, and active motion of the foot indicate that she is making satisfactory progress. The fact that ecchymosis still persists is probably independent of the injury to the bone. Conversion of blood into pigment and absorption may be delayed under circumstances over which we have no control. If she does not make satisfactory progress, please let us know, but the opinion expressed was that she was doing all right and that the blood would probably clear up within the next few weeks. As long as two months may elapse before the blood disappears, according to the literature.

5. *Question.*—Please give me the treatment for inevitable abortion.

(Continued on page 108)

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M. D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of January will be as follows:

January 7—Carbon monoxide poisoning.
January 14—Peanut bronchitis.
January 21—Cause of the common cold.
January 28—Cancer of the breast.

A. M. A. EXHIBITS

Applications for space in the Scientific Exhibit at the next annual meeting of the A. M. A. to be held at Philadelphia next June, should be made to Thomas G. Hull, Director of the Scientific Exhibit, care of A. M. A. Completed application forms should be in the hands of the director by February 20.

1931 STATE MEETING

Three major symposia on Infant and Maternal Welfare, Diagnosis and Therapy, were proposed for the scientific program of the seventy-eighth annual meeting of the Minnesota State Medical Association by the Committee on Scientific Assembly at its first meeting in St. Paul, Saturday, December 13, 1930.

The annual meeting will be held May 4, 5 and 6, at the Nicollet Hotel in Minneapolis with a morning session at the University Hospitals and Medical School.

Members of the Committee present were A. E. Hedback, W. H. Condit, J. A. Watson, E. L. Regnier, W. A. O'Brien, of Minneapolis, Harry Oerting, E. A. Meyerding, St. Paul, P. G. Boman, Duluth, and A. W. Adson, Rochester. Their tentative arrangements for the May meeting provide for the Council meeting, Monday afternoon, May 4, and the House of Delegates Monday evening. Tuesday morning is to be devoted to clinics at the University Hospitals, Tuesday afternoon to the symposium on Infant and Maternal Welfare. The symposia on Diagnosis and Therapy are to occupy Wednesday morning and afternoon sessions respectively.

The annual banquet of the organization is scheduled for Tuesday evening at the hotel.

Dr. Ray Lyman Wilbur, secretary of the White House Conference on Child Health, will be invited to speak at the banquet. Dr. A. B. Kanavel, Chicago, professor of Surgery at Northwestern University and president of the American College of Surgeons, is expected to attend as one of a number of distinguished guests and speakers.

Invitations will be sent out to the entire membership to make further suggestions as to the program and to participate with papers. The next meeting of the committee will be January 24, 1931, at the Nicollet Hotel, Minneapolis.

RAMSEY COUNTY MEDICAL SOCIETY

At the meeting of the Ramsey County Medical Society, Saint Paul, November 24, 1930, Dr. O. W. Holcomb was elected president, Dr. E. V. Goltz, vice president, and Dr. A. A. Schulze, secretary-treasurer (re-elected). Dr. Robert Earl was re-elected Trustee of the Boeckmann Library-Building Fund. Dr. Gordon R. Kamman presented a report of a case of "Alcoholic Polyneuritis with Cranial Nerve Involvement—Korsakow Syndrome" and Dr. Edward Schons gave a paper on "The Significance of Gas Distention in the Diagnosis of Small Intestinal Obstruction and Stasis (illustrated)."

WASHINGTON COUNTY MEDICAL SOCIETY

Washington County Medical Society held their monthly meeting November 11, 1930, at the Stillwater club rooms.

Dr. Emil S. T. Geist, of Minneapolis, the guest essayist for the evening, presented five reels of the original Bohler fracture moving pictures.

If you can visualize a dozen fellows close together in a dark room with only the pictures visible, and Dr. Geist to explain every important point, you can understand how enjoyable those privileged two hours were.

E. Sydney Boleyn, *Secretary.*

SCOTT-CARVER COUNTY SOCIETY

Lieutenant Governor-Elect Henry Arens addressed the regular December meeting of the Scott-Carver County Medical Society at Jordan, December 9, on "Medical Legislation." H. M. Johnson, chairman of the Legislative Committee of the Minnesota State Medical Association, and Mr. F. Manley Brist, investigating attorney for the Minnesota State Board of Medical Examiners, outlined the work of their respective organizations in initiating and enforcing the Basic Science law. Dr. I. J. Murphy, Minneapolis, read a paper on "Radium Therapy."

The next meeting of the society will be held at Chaska the second Tuesday in February.

RED RIVER VALLEY SOCIETY

E. A. Meyerding, secretary of the State Association, and R. M. Burns, St. Paul, were speakers at the annual meeting of the Red River Valley Medical Society, December 9, at Crookston. Dr. Meyerding talked on "Public Relations," and Dr. Burns on "The Trend of Medicine."

Henry Edstrom, Crookston, read a case report on "Myelogenous Leukemia."

The meeting was preceded by a banquet at the Hotel Crookston, to which members of the Ladies' Auxiliary of the society and others were invited.

NICOLLET-LE SUEUR COUNTY SOCIETY

The Nicollet-Le Sueur County Medical Society and the Le Sueur Commercial Club held a joint meeting at the Le Sueur club rooms, December 8, 1930. Mr. F. Manley Brist, attorney for the State Board of Medical Examiners, spoke on medical legislation and its enforcement.

CAMP RELEASE DISTRICT SOCIETY

At the annual meeting of the Camp Release District Medical Society held December 4, E. A. Meyerding, St. Paul, and S. H. Boyer, Duluth, president of the Association, were speakers.

Gregor Schoofs, North Branch, is the new secretary of the Chisago-Pine County Medical Society.

OLMSTED COUNTY SOCIETY

D. M. Berkman, Rochester, was elected president of the Olmsted County Medical Society at the Annual Meeting, December 9, at Rochester. Other officers for 1931 are A. B. Evarts, vice president, and M. C. Piper, secretary, both of Rochester.

WATONWAN COUNTY SOCIETY

New officers of the Watonwan County Medical Society are: W. J. McCarthy, Madelia, president; H. B. Grimes, Madelia, secretary-treasurer; F. L. Bregel, St. James, censor and delegate. The legislative committee for the society includes: O. E. Hagen, Butterfield; Albert Thompson, St. James; and H. B. Grimes, Madelia.

RANGE MEDICAL SOCIETY

The newly organized Range Medical Society, organized under the St. Louis County Medical Society, met Thursday, December 4, 1930, at Virginia. Dinner at the Fay Hotel was followed by a scientific meeting at the City Hall. B. S. Adams, Hibbing, addressed the latter meeting on "Fractures of the Fingers." C. B. Lenont, Virginia, talked on "Blood Transfusion," and C. W. More, Eveleth, on the American College of Surgeons meeting.

Officers of the new society for 1931 are: H. E. Binet, Grand Rapids, president; C. W. More, Eveleth, vice president; C. W. Bray, Biwabik, second vice president; Fred McK. Ruby, Hibbing, secretary.

RICE COUNTY SOCIETY

E. C. Rosenow, Rochester, addressed the annual meeting of the Rice County Medical Society at Northfield, December 11, 1930, on "Poliomyelitis." The following officers were elected: President, J. M. Murdoch, Faribault; first vice president, W. E. Wilson, Northfield; second vice president, Edmond Backe, Kenyon.

Dr. A. M. Hanson, Faribault, was elected delegate, with F. J. Lexa, Lonsdale, alternate.

Censors for the year are: W. H. Rumpf, Faribault; F. M. Babcock, Northfield; M. L. Mayland, Faribault.

The following members were appointed to act on the Publicity Committee: F. M. Huxley, Faribault; P. A. Smith, Faribault; O. P. Thorson, Faribault.

WOMEN'S AUXILIARY
Minnesota State Medical Association

President—Mrs. S. S. Hesselgrave, St. Paul
Chairman Press and Publicity—Mrs. E. A. Meyerding, St. Paul
Editor—Mrs. A. A. Passer, Olivia

The Executive Board of the Women's Auxiliary of the State Medical Association held a regular meeting at the Lowry Hotel, St. Paul, the third of December. Nineteen members attended the session, which was addressed by Dr. E. A. Meyerding of St. Paul. Dr. Meyerding gave an illustrated talk on "The Minnesota Public Health Association and Its Co-relation to the State Medical Association." Mrs. S. S. Hesselgrave, president of the State Auxiliary, gave an interesting report of the meeting of the National Executive Board, which was held in Chicago the fourteenth of November.

The January meeting of the State Executive Board will be of a "legislative" nature. The Legislature will then be in session and the Women's Auxiliary will learn from the State Medical Association what will be expected of it in regard to legislative measures.

CAMP RELEASE AUXILIARY

Camp Release Auxiliary held its annual meeting at Granite Falls the fourth of December. Mrs. A. A. Passer, retiring president, presided at the business session, which was followed by a joint banquet with the Camp Release Medical Society. Speakers at the banquet were Dr. Boyer of Duluth and Dr. Meyerding of St. Paul. Dr. Boyer talked on "Organization," and Dr. Meyerding stressed the work of the Women's Auxiliary and gave that organization many helpful suggestions as to future usefulness. Camp Release Auxiliary has a membership of twenty-six, but due to the fact that the membership is widely scattered the activities have been mainly social. However, there is a growing interest in serious work, without which no auxiliary can long survive. The following new officers were elected: President, Mrs. J. S. Kilbride, Canby; first vice president, Mrs. M. C. Johnson, Dawson; second vice president, Mrs. G. H. Mesker, Olivia; secretary, Mrs. R. C. Adams, Bird Island; treasurer, Mrs. Leon G. Smith, Montevideo.

RAMSEY COUNTY AUXILIARY

The Women's Auxiliary of the Ramsey County Medical Society has issued an attractive Year Book containing the programs for the season. The December meeting was held at the home of Mrs. H. E. Hunt, 1490 Summit Avenue, Saint Paul. A talk on her recent trip to Russia was given by Mrs. Walter E. Ramsey. Following the talk tea was served with Mrs. E. M. Hammes and Mrs. A. G. Schulze presiding at the tea table.

Mrs. H. O. Skinner, 2190 Princeton Avenue, Saint Paul, will be hostess to the Auxiliary in January, and the March meeting will be held at the home of Mrs. Walter D. Brodie, 665 Montcalm Place. The activities of the Ramsey Auxiliary will be concluded in May with a picnic at the summer home of Mrs. Henry N. Klein, at Turtle Lake.

Mrs. E. M. Hammes is president of the organization. Committee chairmen appointed by Mrs. Hammes for the year are Mrs. C. K. Williams, philanthropy; Mrs. Karl Dedolph, program; Mrs. H. E. Binger, hospitality; Mrs. Philomen Roy, membership; Mrs. W. H. von der Weyer, ways and means; Mrs. J. Richards Aurelius, telephone; Mrs. H. O. Skinner, publicity; and Mrs. M. Keller Knauff, year book.

HENNEPIN COUNTY AUXILIARY

The Women's Auxiliary of the Hennepin County Medical Society held its annual Christmas party December 17 in the library of the society in the Medical Arts building, Minneapolis. Christmas carols were sung by a group of the members under the direction of Mrs. C. O. Maland. Two of the artist members of the auxiliary, Mrs. E. T. W. Boquist, soprano, and Mrs. Ivar Sivertsen, reader, gave the program. After the program a Christmas tea was served, arrangements for which were made by Mrs. Emil Geist, with Mrs. J. M. Lajoie as co-chairman.

We quote from the American Medical Association Bulletin the following ten points by Dr. H. W. Salus of Pennsylvania concerning the worth of such an organization as the auxiliary:

1. The Pennsylvania Auxiliary has made more progress in six years than the men's society in sixty.
2. The doctor used to bring his wife to conventions. Now the wife brings the doctor.
3. The auxiliary has added polish and refinement to these gatherings.
4. It has created a better bond of fellowship among the men and a lasting friendship among the women.
5. It has permitted the woman to become an integral part of the life of the man, socially, professionally and commercially.
6. It has spruced up the appearance of the men.
7. It has interested the local merchant and brought him business.
8. It has given the doctor much-needed rest and recreation in the midst of his serious scientific meetings.
9. It has brought daughters into more intimate relations with the medical interests of the family life.
10. It has stimulated the medical society not to be outdone in thought and activity.

HORMONE AND CANCER

The effort to influence the growth of cancer by various organ extracts is being widely made at present. Logically it might be profitable to inquire why such trials are being made, since every pathologist sees cancer growing freely in those organs whose hormonic activity is high. The work of Bishoff and his colleagues should be repeated with a tumor that does not spontaneously recede and, if the results are the same, should close the discussion on the possible therapeutic action of extracts from the group of organs tested. (Jour. A. M. A., November 1, 1930, p. 1350.)

PROCEEDINGS MINNESOTA ACADEMY OF MEDICINE

Meeting of November 12, 1930

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, November 12, 1930. Dinner was served at 7 o'clock and the meeting was called to order at 8 o'clock by the President, Dr. E. S. Geist.

There were 43 members and 2 visitors present.

Minutes of the October meeting were read and approved.

The scientific program of the evening consisted of two theses and four case reports, as follows:

Dr. Alexander Stewart (St. Paul) read his Thesis entitled "Observations on Serotherapy in Scarlet Fever." (To appear in Minnesota Medicine at a later date.)

DISCUSSIONS

Dr. W. R. Ramsey (St. Paul): I think Dr. Stewart has covered the field very well. The effect of the serum antitoxin in the severe cases is very marked; as he said, it is sometimes spectacular. The disease is so treacherous that one is warranted in giving the serum, and now that the dosage is so small, that is, so concentrated, one is not likely to get serum sickness. The matter of prophylaxis is still very much in doubt. Parke, Zingher, and others have come to the conclusion that this is still in the experimental stage and have given no definite conclusions, but they hope to have collected enough cases and data to have something definite in the next year or two. Some of these cases do get a terrific reaction.

Dr. Frank Wright (Minneapolis): My experience with scarlet fever is limited to one case in which I was particularly interested. Eight years ago this child, then five years old, developed scarlet fever. She had a temperature of 104° and two nurses constantly for five weeks. She developed an adenitis—both sides of her neck—and a double otitis media and apparently was going to die. As a last resort it was decided to give her some foreign protein therapy. Not being able to find horse serum in the Twin Cities at the time, she was given diphtheria antitoxin. Her temperature had been 104°, and after this first dose it dropped to 102° in six hours. After the second dose her temperature dropped to normal and stayed normal, and in two weeks she was able to be taken south. Now whether or not it was due to diphtheria antitoxin, or the use of foreign protein, or whatnot, she got well.

Dr. H. T. Nippert (St. Paul): I should like to ask Dr. Stewart how he gives the serum, whether intramuscularly, intravenously, or subcutaneously; in very toxic cases would he advise the intravenous use?

With reference to Dr. Wright's remarks, I might add that before scarlet fever antitoxin came into use we had sometimes used diphtheria antitoxin and got fairly good results. We also used antistreptococcic serum and thought we got fairly good results with that too.

Dr. Stewart (in closing): Answering Dr. Nippert's question as to the method of administration, we give the serum intramuscularly except in some of the late cases we give it intravenously. The first serum that came out we gave intravenously. I recall one case which I tried giving it intramuscularly, before the serum was made up in the concentrated form. It took me about an hour and a half to give that much. We formerly had a lot of trouble and quite a lot of reaction.

In connection with Dr. Wright's remarks on the use of diphtheria antitoxin, we have used that a number of times and thought we got good results, but we get better results from the specific serum.

Dr. William H. Hengstler (St. Paul) read his Thesis on "Neurological Aspect of Head Injuries."

DISCUSSIONS

Dr. A. S. Hamilton (Minneapolis): I have listened to this discussion with great interest and think Dr. Hengstler has covered the subject fully, clearly and conservatively. It is certain that the number of head injuries one sees has increased in recent years; at least those that are classified in reports under the heading of fractures of the skull are so increased. No doubt the coming of the automobile and the speed at which it is driven is to blame for much of this increase, but the *x*-ray also is responsible for many of these reports. At least, it seems to me that what we now call severe fractures of the skull were in my early days called fractures; and those cases which we now see, where one physician sees a line and calls it a fracture and another physician, equally skillful and equally honest, sees the same case and doubts the presence of fracture, were all called concussion without question.

Of course, the *x*-ray has done a great deal to aid us in diagnosis but it is not the fracture of the bone which determines the severity of the injury; it is the degree of involvement of the brain covering, of the blood vessels, of the cranial nerves, and of the brain tissue itself, which determines the severity of the head injury, and here the *x*-ray does not help us greatly. In determining the severity of the injury, one must give close attention to the degree and duration of the unconsciousness. If the patient is in a condition of coma or even of profound stupor and remains so for two or three hours or more, it seems to me that we must assume something more than an ordinary concussion. Of course, in a world where nearly everyone seems to be insured, it is often difficult to get the exact facts. As an illustration of this, I was yesterday looking over two records of the same man. One was given by the man himself in which he recorded a statement of absolute unconsciousness for three hours following his injury. The other report, made by the man who assisted him, stated that he went for help directly after the accident and returned in ten minutes. The patient was sitting up and was conscious. With assistance, he got into an automobile and was driven several miles to a hospital. He was an Irishman and in the course of his journey, he laughed and joked, remarked that you could not kill an Irishman, smoked a cigar and was finally delivered in a conscious condition at the door of the hospital. This does not prove that the man was lying, for, in head injuries, all incidents are sometimes blotted out of the memory for a certain time so that the patient cannot go back and reconstruct his life. Certainly, however, the case where the man responds in a clear-headed way, even though he cannot afterward recall what happened, is very different from that one in which the individual is in a profound coma for a considerable period. Where there is loss of the deep reflexes and marked pupillary changes, including failure of the pupils to respond to stimuli, the case is certainly serious.

Unfortunately, it is very difficult at the present time to find any statistics which would be generally accepted as to what the results are likely to be in the average case of head injury. As I have already remarked, we are so generally insured against injury and the desire for a little compensation is so widespread that a motivating psychologic factor is very likely to develop symptoms which at best are often largely of a subjective character and keep alive these distressing phenomena which, without the compensation situation, would certainly long ago have disappeared.

Dr. Hengstler has referred to epilepsy following head injuries. Unfortunately, here again, we have no reliable statistics on which we may depend to determine the likelihood of epilepsy in any given case. I have seen statistics where epilepsy is said to have developed in cases of head injury with fracture of the skull in as high as thirty per cent of cases. Judged by my own experience, such a statement is ridiculous unless the author is dealing with a specially selected series of very grave cases. Like the author, as I understand him, I look upon epilepsy as a situation where there must be some fundamental constitutional condition and if trauma is to be looked upon as a cause of epilepsy, if the above opinion is correct, it must be looked upon only as a precipitating or exciting cause and not as the primary cause. I have, however, seen cases of convulsions of generalized character developing in cases following head injury where I can hardly assume the relationship was merely coincidental and I have felt that sometimes injury to the brain may bring on generalized convulsions.

What is known as delayed hemorrhage constitutes an interesting feature in a very limited percentage of head injuries but a sufficient number of cases have now been reported so that one cannot doubt their existence. The period between the time of injury and the onset of the cerebral hemorrhage may be anywhere from a day or two up to as long as a few weeks and it is worthy of note that in the cases of delayed hemorrhage reported there has frequently been found evidence of pathological conditions in the vessels so that the injury would have been looked upon ordinarily as only a precipitating cause.

Dr. J. F. Corbett (Minneapolis): I enjoyed this essay a great deal. As the paper was read, there went before my mind the positive indications for operation. First and foremost is the case where progressive symptoms develop, where there is a little bleeding from a vessel outside of the dura. The patient may develop paralysis, aphasia, unconsciousness, and finally reach the stage of medullary compression and die. These cases are common causes of death in head injuries. In the statistics of Le Cont in Cook County, a major part of the deaths from head injuries were attributed to extradural hemorrhage. The cure is operation. The operation is in simply removing the clot, if necessary the ligation of the vessel, and the outcome is pretty fairly good. I have had an opportunity to do this a little over thirty times and have had two deaths, and both of these were cases that reached the stage of medullary compression. Another indication for immediate operation is where there is a compound fracture. Thorough immediate débridement is imperative.

But there is another condition which demands immediate operation and that is a fracture extending into the sinus into the frontal bone. I recently had a case where an abscess developed into the frontal region that came from such a crack being neglected. Depressions are commonly corrected by elevation or removal of the fragment.

The spinal puncture needle is very valuable and I had certain rules at the General Hospital to follow in the use of spinal punctures, but every once in a while somebody would go wrong and use the spinal puncture where it should not have been used. There are cases where it should not be used. First, if your patient is in shock, do not use the spinal puncture. Second, if there is threatened embarrassment of the medullary centers, do not use spinal puncture. And, third, although it is difficult to lay down exact rules for diagnosis, where there is bleeding in a large vessel in the brain or skull you may get a fatal ending from using spinal puncture; but I do not know how you can anticipate that in advance.

Dr. Herbert Jones (Minneapolis): It seems to me this paper is very opportune at this time. We formerly had the injuries caused by horses and those were direct accidents. Then we passed into an era of railroad accidents in which the large element was that of shock. The saying among the old railroad surgeons was that the injuries were so severe that the tissues were shocked and the patient did not do well. These accidents have been largely overcome by the railroads. We are passing now into the age of automobile injuries. When an automobile hits a person that person is temporarily unable to control his head; that is, the head hits the ground or some object and we get the peculiar head injuries that we see in ever-increasing numbers. Those accidents are especially in the neurologist's field to deal with, as there must be a competent diagnosis in order to decide whether the person is so shocked that the outcome will be fatal if operated. A certain number must be operated upon in order to prevent devastating hemorrhage into the brain tissue. And the decision is a very important one. This paper is a very timely one.

Dr. J. C. McKinley (Minneapolis): Martland published an article on "Punch Drunk" in the Journal of the A. M. A. in October, 1928, which seems to me to bring up a point which is not appreciated in our consideration of concussion and contusion of the brain. He calls attention to the high incidence of commonly progressive neurologic syndromes (ataxia, tremors, Parkinsonian states) in prize fighters, especially those of the rough-and-tumble type of poor boxer who takes much head punishment over a considerable period of time. He thinks that the symptoms are due to petechial hemorrhages in the brain. Now we usually think of the knockout in a fight as a pure case of concussion without permanent injury, but obviously from Martland's observations a small amount of permanent damage is done to the brain with each knockout blow. The effects are cumulative until a full-blown neurologic picture develops. This indicates the difficulty, if not impossibility, of separating concussion, with its temporary effect of loss of consciousness, from contusion, with its permanent anatomical and often functional damage. One should be guarded in a given case in speaking of a concussion without contusion, as it is doubtful if such a circumstance actually occurs.

Dr. A. W. Ide (St. Paul): In our experience in railway work, head injuries have been becoming more and more infrequent. The few injuries that we do see are not caused by accidents incident to the operation of trains. Occasionally some one is injured as a result of a speeder accident. These speeders are small gasoline inspection cars. In spite of every precaution, the light cars sometimes leave the rails and throw the passenger from his seat.

It seems to me that one of the greatest problems in connection with head injuries is getting the men back on the job. Headache and dizziness persist and are very annoying. Patients are apt to be uncertain of themselves. They doubt their ability to continue work over prolonged periods.

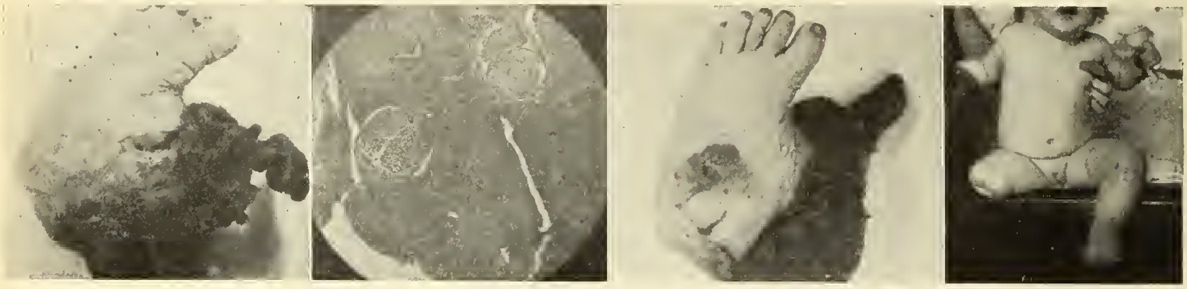
A sympathetic attitude on the part of the physician is very necessary. These patients need encouragement.

Dr. Hengstler (in closing): I appreciate very much the discussion of this paper and wish to thank the gentlemen for it.

I want to say that I agree most heartily with what Dr. Corbett said about the use of spinal puncture, believing that spinal puncture should be used, but used with discrimination; and I agree with him that in cases of free intracranial hemorrhage, its outcome cannot be foreseen.

With respect to epilepsy, my experience with this following head injuries is somewhat limited. The cases that I have had have all been in connection with litigation and the patient was claiming epilepsy as a result of the head injury. Some claimed types of grand mal and some of petit mal, but in each instance investigation proved these individuals came from epileptic families where the history had been covered up. One can conceive of an individual who had epileptic parents and who has an epilepsy in abeyance, and then who experiences an accident which lights up this epilepsy. That, I think, might be admitted, but in my cases where they had true epilepsy following head injury, it has always been of the Jacksonian type. I think my experience has been too small, perhaps, to make a definite statement about the matter of epilepsy. In the cases brought into court, there is no question but what a thorough investigation should be made of the family and antecedents to prevent concealing a history of previous epilepsy.

Since writing this paper, and within the last two months, I have helped take care of a woman who was injured in St. Paul, and who was in a state of unconsciousness for fifty-two days, and finally died of pneumonia. She was brought into the hospital with a respiratory rate of four per minute, and a pulse in the fifties, and in profound shock. We decided on a spinal puncture and drained off 60 c.c. of bloody fluid. She improved following the first puncture and we continued these. After some days of bloody fluid, it began to clear, going through the characteristic changes, and the woman seemed on the road to recovery. She never got beyond a certain point, however. Her eyes were open and she would take food, but she knew nothing of what was going on around her. Those of us who were seeing the patient right along advised against opening the head, but her husband had friends who were very insistent upon it. We did not yield, however, and at autopsy our judgment was proven correct. The skull was opened and she had no clots of any kind, intracranially, but the right cortex was very badly lacerated, and had she lived, of course, she would never have regained normal mentality. In this case we were fortunate, at autopsy, in getting the evidence which proved that the proper therapy had been used.



a b c d

Fig. 1

Dr. H. P. Ritchie (St. Paul) gave the following three case reports:

1. A Case of Prenatal Sarcoma.
2. Multiple Congenital Clefts of the Face.
3. A Transplant of the Female Breast.

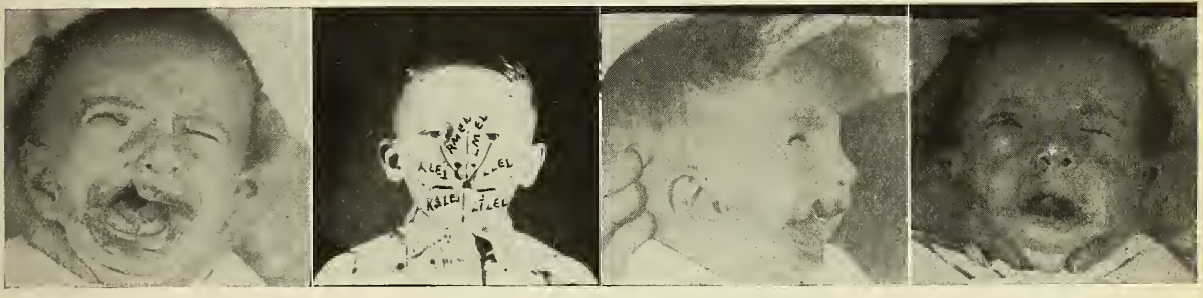
I have three cases which I believe are worthy of our permanent records.

Case 1 is that of a baby born on June 20, 1929, at Pine City, Minnesota, under the care of Dr. Stratte. There is nothing in the family history that would have any bearing on the case. The carrying period was normal; the confinement was normal. Subsequent to birth, Dr. Stratte remembered that the amniotic fluid as it was evacuated was distinctly bloody, but this was not noted at the time for obvious reasons. The baby was born white with a large outgrowing spongy, bleeding tumor which involved the right heel and foot. A tourniquet was placed on the leg and as soon as the mother was cared for the baby was transported to the Children's Hospital in St. Paul, where it arrived about two hours after birth. Dr. Ray Shannon saw the case appreciated the critical situation and transfused with the father's blood. Blood count, hemoglobin 48, reds 1,790,000, blood grouping IV. I was called in to pass upon the possibility of surgical procedures other than amputation. The indication for this operation appeared imperative. After another transfusion, the leg was amputated in the lower third at the fifth hour of the baby's life. The specimen was given to Dr. Kano Ikeda, who made many sections of this tumor. Figure 1b is a photomicrograph of but one of several sections made. It shows a densely cellular tumor with nerve fibers, greatly enlarged, running throughout. Dr. Ikeda's report, copied from the history, is as follows:

> "A soft fungoid mass about 6 cm. in diameter protrudes out of the tibial aspect of the right foot and along the inner surface of the ankle. The surface of the mass is rounded and devoid of skin. The plantar aspect of the mass is irregular and broken. The cut surface shows a soft whitish cellular tissue with areas of hemorrhage. The tumor tissue infiltrates diffusely through the soft tissue of the tarsal portion of the foot. The aspect of the os calcis appears broken through by the tumor growth, while a cordlike trunk 1 cm. in diameter is present along the course of the tendo achillis. The tumor is composed of compactly arranged bundles of large pale staining spindle cells running in all directions. Many mitotic figures are noted. Diagnosis: Spindle-cell sarcoma."

Examination of the gross specimen showed that the amputation was through or so near to the tumor that, should the baby live, recurrence would surely follow. The tumor had extended, pushing aside the neighboring tissue alongside the tendon of Achilles up into the leg. The father was frankly told that the operation was unsatisfactory and incomplete. Re-amputation assumed the aspect of a moral problem. Was it justifiable to further mutilate this infant in the presence of such an active malignant growth? I decided to be influenced by the solution of two questions. Had metastasis already taken place? *X*-ray studies of the lungs were made and were negative. The question of icterus was run down and its presence disproven. The second question was whether the new growth was primarily an osteogenetic tumor? Rightly or wrongly, I have carried in my head the idea that primary bone tumors of the sarcomatous type were eventually lethal. The few cases which have come under the care of Dr. MacLaren, Dr.

Daugherty and myself are all dead, no matter what the point of amputation. The bones of the foot were found to be involved. This question was carefully considered by Dr. Bell and Dr. Ikeda with the conclusion that they were secondarily and not primarily involved. The father was most understanding and coöperative, and I received permisison to re-amputate. The point of amputation received consideration as to whether it should be undertaken in the leg or above the knee. I finally decided that the question was critical and so amputated on the fifth day of the baby's life in the lower third of the femur. The baby was bundled up and taken from the operating table back to its mother in Pine City. Under the care of Dr. Stratte this baby has now developed into a husky beautiful child, fourteen months old at the time of taking the picture in Figure 1d.



a b c d

Fig. 2

The value of this case from a surgical standpoint is nothing. These cases must be very rare, but we have not made a complete survey of the literature in this respect. Possibly there are many cases which have not reached the literature. From an embryonal standpoint it is interesting to speculate upon the cause of such a luxuriant growth developing to such a point in utero. It may have some bearing upon the theories of the formation of new growths. I presume from a pathological aspect the proper procedure will be to send all this data to the Sarcoma Commission for further consideration. From a clinical standpoint, the circumstances and problems of this case were as dramatic as in any of my recent experience.

Case 2 is a baby now four months old which shows multiple congenital clefts of the face. In Figure 2a a cleft appears in the right upper lip, commonly described as "harelip"; also a cleft at the right angle of the mouth extending into the right cheek, and a cleft of the left angle of the mouth extending into the left cheek. In Chapter IX, Volume V of Lewis' System of Surgery, I have had the wonderful opportunity to review some of the problems in the field of congenital clefts of the face and jaw. As I read that chapter in cold print I am startled at the controversial tone of it, the indirect and uncertain language of several statements and the over-emphasis on certain parts of the technic. But there is one part which I believe may very well be greatly enlarged. Part II of the chapter is entitled "A Surgical Interpretation of the Embryology." This is the product of a study undertaken through the interested help of Professor R. H. Scammon with a definite purpose to relate the embryology of the upper face and jaw to the surgical problems of this locality. I am in no position to talk embryology. I am still uncertain as to how much of the data recognized as principles of growth is incontrovertibly established; how much of the evidence is due to the direct study in the human embryo; how much is indirect evidence taken from the lower animals and applied to the human embryo. There is, however, a general agreement that the face is formed by the contact, union, or coalescence of separately developing groups of embryonal tissue. In embryological terms these are called "processes." The mandibular processes form the lower jaw, the maxillary processes and the frontal-nasal processes form the upper jaw. In the effort to carry embryology to our clinical problems it seems to me that we should have a broader term of description of the embryonal groups, so as to include all elements, no matter whether it is skin, muscle or mucous membrane, or bone, or whatever kind of tissue, because there is here found all of the superficial tissues of the body and which at some time require surgical attack. In searching for a substitute term, the word "division" was selected as being broad enough to include all elements under consideration for surgical repair. In Figure 2b are marked lines and letters inserted upon a photograph of a bilateral cleft lip. This particular case was selected because the clefts are exactly symmetrical; thus the prolabium of the median embryonal division is beautifully outlined. It is necessary to follow this figure while reading the description.

The lower jaw is formed by the union of the mandibular processes, here described as the right and left inferior lateral embryonal divisions. Should there occur a failure of union of these two divisions, a cleft will result. This cleft must be a median cleft and is here represented by a straight line in the lower lip. The upper jaw has a right and left lateral embryonal division exactly similar to the lower jaw. A failure of union between the right or left superior lateral embryonal division and the right or left inferior lateral embryonal division will result in a cleft at the angle of the mouth, right or left. These clefts likewise must be straight lines because, as in the lower jaw, only two embryonal divisions are concerned in the union. Unlike the lower jaw, the upper jaw has a third division which is called "the median embryonal division," inserted in between the right and left laterals. Growth is further complicated by the fact that the division has two points of origin so that the right median embryonal division has a different origin from the left median embryonal division. For instance, the alar cartilage of the right nose has a separate origin and growth from that of the alar cartilage of the left nose. So it is perfectly possible to have a failure of proper union between the right and left median embryonal divisions. Should this occur there follows a cleft nose, a cleft columella, a median cleft in the prolabium and pre-maxilla. All of these tissues are derived from the median division. These clefts should be straight-line clefts for the reason that again only two divisions are involved. The common harelip or cleft lip is formed by the failure of the right superior lateral to unite with the right median, producing a right cleft; or the left median to heal with the left superior lateral, producing a left cleft; or both appear in the same case. These clefts are always definitely lateral because they appear to one side or the other of the median division and therefore should be in oblique planes. These latter clefts may also extend into the face and up to involve the lower eyelid on either side or both sides. Every human embryo that starts life may have any one or all of six possible clefts, as shown by noting the lines on the diagram.

A review of this case of multiple clefts reveals that the right superior lateral embryonal division is out of contact with both the inferior and median neighboring divisions. The obicularis of the lip, on the superior right, which stands out definitely as bunched muscle, is entirely out of contact. It has failed to unite with the right inferior muscle and the cleft in the cheek results. It has failed to migrate underneath the skin of the prolabium to come in contact with the muscle which has normally migrated from the left lateral, and a harelip results. There is a suggestion of a cleft continuing from that of the lower lip up through the face to a small but appreciable angle in the lower lid. There is also a dermoid of the right eye.

The surgical indications are beautifully outlined and indicate that repair should be made on the muscle principle. In my series I have a cleft nose, I have seen illustrated the cleft columella, I have two perfect median clefts of the prolabium, I have many cases of harelip, both unilateral and bilateral, I have seen illustrated a cleft of the lower lip, and here is a case with the clefts at each angle of the mouth; thus all the lines drawn on the diagram have been clinically demonstrated. Whether or not the surgical interpretation of the embryology can be supported in detail, the statements here made, taken merely as a theory, fit into so many conditions that I believe they are worthy of mature consideration.

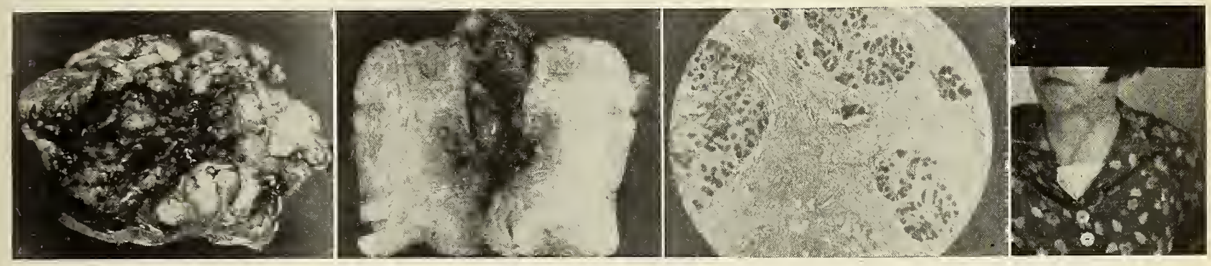
Fig. 3

Case 3 is one to which I call your particular attention. In 1918, a girl five years old was brought to Dr. MacLaren, Dr. Daugherty and myself, suffering from a burn contracture of the neck, of a degree in which the chin was anchored to the manubrium. Two double-ended flaps were outlined—one on the right chest and one on the left shoulder and arm. The distal ends were gradually severed and when freed were placed in the form of a cravat on the denuded area which followed the dissection of the contractures of the neck. There is no picture of the original condition; indeed, one may not have been taken. We were not so careful of pictorial records then as we are today. Figure 3a is a photograph of the girl as she left the hospital and from this it will be seen that the flap from the right chest was placed at the chin and that from the left shoulder at the manubrium. Nothing was heard of the girl except an occasional indirect report that the operations were satisfactory.

On July 15, 1930, the girl with her mother appeared at my office. She had grown into a husky young lady, a junior in high school. She gave a history that everything was well until about four years previously, when the neck began to show gradual and progressive enlargement. Figure 3b is a photograph of the right side showing the very full, rounded neck and also the scar on the right chest. She wore a black band about her neck. When this was removed I was startled to see a well-developed mature nipple in the suture line shown in the front view (Fig. 3c) and left side of the neck (Fig. 3d) in which the nipple is more definitely shown. It is interesting to note that the enlargement had extended underneath the tissue of the left flap, which is very well outlined in this photograph. It took me quite a time to determine the situation. Palpation of the neck revealed a definite organized body under the skin and movable on the deep structures. Evidently in the first operation we were more concerned about the length of the flap and the fitting of it into the raw surface than we were in the tissues contained therein and had unwittingly included the immature infantile breast in the flap and had perfectly encircled the whole nipple and mammary gland leading into it. When puberty occurred this gland developed normal physiological enlargement.

The surgical problem was first, the question of replacement of the gland to its normal location. I knew of the elaborate procedures necessary to obtain tissue to substitute this beautifully placed flap and the time required to do so. The thing that decided me was the question of whether this gland was really a functionating structure and whether it would pursue its normal course should it be replaced. I finally decided to remove it. The next day a half-moon incision was made to remove the nipple, the tissues of the left flap were reflected backwards and a line of cleavage underneath this growth was then determined. At one time during the operation I had the identical picture of an ordinary mastectomy; the only difference being that the base structures were those of the neck instead of the pectorals. The usual care of dissecting the skin to prevent buttonholing and consequent scar was exactly the same. Figure 4a shows the mass removed with the nipple at the lower part of the specimen. Unfortunately this photograph was taken after it had been in a preservative, but it gives the ordinary picture en masse of the normal breast. Figure 4b shows the growth bisected; the size, the contour and the consistency illustrates a familiar picture. Figure 4c is a photomicrograph taken at random showing the regularity of the acini lined with deeply-staining cells and, although the interstitial tissue may be exaggerated, it surely has the picture of a normal breast.

The clinical value of this case, of course, is nothing. I cannot imagine a situation that would require the purposeful transplant of a female breast, but as a case bearing upon some of the questions and principles of tissue transference, it may be of great value. The recent literature upon the subject of transplants indicates that there is a more general recognition of the fact that the free-graft principle of transference is entirely different from that of the flap. The cellular structures of a flap, properly prepared and placed, are always live elements nourished by channels of supply approximately the same as when in their original position and the margin of chance is very broad that these structures will pursue in the new location their normal growth, physiological action and anatomical change, almost exactly similar to their behavior before the surgical attack. Quite contrary consideration must be made of the elements of a free graft. The normal bed of this tissue is completely severed and a new field invaded. Anatomical structure must be maintained by the formation of entirely new avenues of nourishment. The margin of failure is enormously widened unless meticulous care is exercised to obtain the most favorable conditions for the formation of new sources of nourishment and the physiological life of these cells revived at the earliest moment or anatomical death results and a failure of the surgical purpose follows. The behavior of the tissues of a free graft, of whatever nature, is by no means settled. There is a great question how many of the original cells revive and follow through their normal growth, how many are substituted by scar tissue, how much of a so-called successful result of a free graft is really due to growth of the original tissue, and how much is due to the possible stimulation of growth of other tissue.



a b c d

Fig. 4

There is one division of this subject, however, where these considerations have been entirely disregarded, *viz.*, the transplant of glands. From a surgical standpoint the claims made for these procedures have exceeded the possibility of tissue transference. Glands have a complicated anatomical structure. They have intricate physiological function, depend for their activity upon direct arterial blood supply, and have a definite system of absorption. We are told that these are all severed and, on the principle of a free graft, these tissues are then placed in another location with the expectation that this complicated anatomical arrangement will be maintained and the physiological action restored. Indeed, it is suggested that the glands be placed in muscles, that the outer surfaces be scarified in the hope of obtaining new channels of nourishment; but when looked at from the principle of free graft and the flap, it seems to me that a gland so transferred can only have temporary effect, must either degenerate or become encysted as a foreign body, and that the clinical results reported following such procedures must be, in the main, psychological.

The mammary gland is the least complicated of any, but if it had been completely severed from its attachment and placed in the neck or elsewhere it would not have given the picture here shown. In this case the mammary gland was at no time severed from its original blood supply. Possibly some part of it may have been cut away, but at all times it has been living tissue, and during the years new channels have had time to form and consequently when puberty took place we see physiological enlargement. The explanation of its growth in this case appears logical and reasonable and I believe that this gland would have been activated in its odd position by pregnancy.

There is a chance for some one to make complete revision of the whole field based upon the physiology of the cell or groups of cells included in the transplant.

Dr. Arthur W. Ide (St. Paul) reported the following case of Prenatal Sarcoma, and the baby patient was presented before the Academy.

The patient (Baby B.), a girl, is now 35 days old. She was born in the Northern Pacific Hospital, St. Paul, Dr. H. G. Collie attending.

At birth a tumor was seen involving the left leg. This growth measured 16½ cm. in length and 23½ cm. in circumference. It was situated on the anterior surface of the knee and extended upward onto the anterior surface of the thigh and downward on the anterior surface of the leg. There was a small ulcer on the anterior surface of the tumor. General examination showed the baby to be normal except for this tumor. She weighed 7 pounds 12 ounces at birth.

Family History: The parents are both living and are strong and healthy. They have one other child, a boy three and a half years old, who is perfectly normal, well and strong. There is no history of syphilis, rheumatism, gout, tuberculosis, epilepsy or malignant disease The paternal grandmother died of Hodgkin's disease.

The patient has been at home and cared for by the mother except for the first ten days of her life. She now weighs 7 pounds 8 ounces—four ounces less than her weight at birth.

The tumor has not enlarged since birth. The ulcer on the anterior surface of the tumor has extended. It is now 2.5 cm. in diameter.

Diagnosis: The patient was seen by Dr. E. T. Bell, who considered the tumor to be a sarcoma.

It is very probable that the growth is malignant. The *x*-ray indicates that the bone is not the primary seat of the growth. It is firm in consistency. A biopsy so far has not seemed justifiable and for this reason we cannot state definitely the nature of the growth.

The meeting adjourned.

R. T. LaVake, M.D.,
Secretary.

VIOSTEROL

Holtz and Schreiber of Göttingen have reached the conclusion that irradiation of ergosterol produces a number of distinct substances. One is the antirachitic factor, perhaps Vitamin D proper; another is a separate component producing calcification. The two effects, antirachitic and toxic, can be separated; or at least one can be destroyed while the other remains intact. If these observations prove to be correct, they may lead to a desirable purification of viosterol so as to eliminate or diminish the "toxic" features of its action. (Jour. A. M. A., November 22, 1930, p. 1593.)

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

Meeting of November 6, 1930

Dr. A. T. Mann, President, presiding.

The regular monthly meeting of the Minneapolis Surgical Society was held in the Lounge of the Hennepin County Medical Society, on Thursday evening, November 6, 1930. The meeting was called to order at 8 p. m. by the President, Dr. A. T. Mann. There were 26 members and 6 visitors present.

On account of the length of the program, the reading of the minutes of the October meeting was omitted.

The scientific program was as follows:

Dr. John Rishmiller presented a case report on "Habitual Dislocation of the Shoulder, and the Clearmont Operation," with a general discussion of shoulder joint injuries. (To be published later in the International Jour. of Med. & Surg. and the Surgical Journal.)

Drs. L. H. Fowler and Wm. A. Hanson gave the following report of a case of "Embolic Gangrene of the Foot," the report being read by Dr. Hanson, after which the patient was presented.

The patient was a man aged 54 years, whose past history was essentially negative. On February 4, 1930, he had severe sharp pains in the arms, back and chest, at the level of the nipple line, which were not related to exercise. He had many carious teeth with recession of the gums, gingivitis and pyorrhea. Examination was otherwise negative.

On February 22, 1930, he had six lower teeth extracted, with no reaction following. On May 20, 1930, he had six upper teeth extracted, one surgically, with curettement of the sockets. On May 22, 1930, he began to have sharp pains over the chest of a stabbing character, with clonic contractions of the neck, chest and arm muscles. Six days later he had an increase in temperature to 101°, pulse 95. At this time he complained of pain over the dorsum of the right foot between the large and second toes. There was a small abrasion with an erythema about this area. He had marked hyperesthesia over the dorsum of the foot extending to the outer surface of the ankle. On May 31st he developed a temperature of 103° with a serosanguinous bleb about 3 by 4 inches in diameter over the dorsum and lateral side of the foot. Also a similar bleb 1 by 1 inch appeared over the medial surface of the foot. The whole foot and leg below the knee became markedly swollen, red and indurated. The patient was very toxic, delirious, with a temperature of from 103° to 104° for several days. General supportive measures were instituted. The foot and leg were treated by elevation, hot packs, Ochsner's solution for 24 hours, and then continuous irrigation with Dakin's solution. His general condition gradually improved. The cellulitis of the foot and leg cleared up. The skin and subcutaneous tissue of the dorsum and the lateral surface of the foot sloughed away, exposing the extensor tendons. Eventually, clean healthy granulation tissue appeared over this area.

On June 24, 1930, a full thickness skin graft was done. This was not successful, probably owing to the impaired blood supply to the part. Later, Thiersch grafts were applied with very satisfactory functional and cosmetic results. The patient has a practically normal foot today.

Careful examinations by medical consultants have failed to disclose any pathology in the heart or lungs. All laboratory examinations, including urine, blood, blood culture, *x*-ray, and electrocardiogram were negative.

The pathological process was apparently due to a blocking of some of the smaller terminal vessels of the dorsalis pedis artery by infective or bacterial emboli originating from infection around the teeth.

DISCUSSION

Dr. L. H. Fowler stated that this was a "rapid-fire" fulminating condition. In February the patient had had no trouble following the extraction of six teeth which were pulled on account of marked infection of the gums around the teeth. Three months later he had six more teeth extracted, and in six days the acute chest condition developed, which was apparently due to showers of small pulmonary emboli. Two days later he developed the lesion on the dorsum of the foot, particularly localized at the base of the great toe. First there were blebs on the skin. Soon the whole foot became edematous, and extensive cellulitis developed extending practically up to the knee. Within four days the whole dorsum of the foot was gangrenous. Eventually the superficial tissues of the lateral side all sloughed off down to the extensor tendons. The skin on the medial side of the foot retained its vitality in spite of the subcutaneous tissues being necrotic and infected.

Dr. Fowler called attention to two or three interesting phases of the case. Surgically, it did not present such a difficult problem except combating the infection. Part of the skin grafts used followed Dr. Wangensteen's method of cutting the Thiersch grafts into small bits and burying them in the granulation tissue. They took, and there is practically no difference today between those and the other areas where whole Thiersch grafts were applied.

Dr. Fowler said that the pathology in this case was interesting: How did these emboli get there? The gangrene was localized to the distribution of the arcuate artery, a terminal branch of the dorsalis pedis, and must have been due to an infective embolic process. He stated further that he had found very little in the literature on this subject; only one case in recent years and that was a case of gangrene of the toes following tonsillectomy and reported in 1929 by Wright, which was associated with a subacute bacterial endocarditis. Dr. Fowler's patient never had any signs of a heart lesion. Pathologists say that very rarely emboli follow operations on the head and neck.

The speaker felt that the only logical explanation for this case just reported was that it was due to a bacteremia coming from the infected teeth, with the bacterial emboli lodging in these terminal vessels and causing the gangrene.

Dr. E. A. Regnier asked how Dr. Fowler accounted for the chest pains?

Dr. Fowler thought this was due to showers of small pulmonary emboli, and added that the patient had had four or five attacks of these sudden severe pains in the chest since he had been at home, but at no time had there been any definite findings in the lungs or in the heart.

Dr. R. C. Webb asked if an electrocardiogram had been taken.

Dr. Hanson stated that an internist had gone over the heart very carefully and there had been *x*-rays and electrocardiograms taken, all of which were negative. He also added that at no time were the toes or sole of the foot involved.

Dr. J. M. Hayes stated that he had been using the so-called Ochsner (or modified Ochsner) method of treating infections of the extremities for many years; and he knew of no one who had ever used it properly, going back to the old method of using plain hot packs for this purpose. Dr. Hayes felt that there was no doubt of its superiority over the use of the ordinary hot pack.

Many years ago Dr. Ochsner had observed this dressing used with saturated boric acid alone and the results were so satisfactory that he was led to do some experimenting with it. He observed that boric acid appeared in the urine after this dressing had been on a few hours. Taking bacteria from the wound before the pack was applied, and injecting them into the peritoneal cavity of a guinea pig, caused the death of the guinea pig in 24 hours. After this dressing had been on for 48 hours, bacteria from the same wound injected into the peritoneal cavity of a guinea pig failed to cause any disturbance.

Dr. Hayes stated that he and his associates had also carried out some of these experiments and obtained the same results. He added that, although the boric acid alone gave good results, he found that the addition of alcohol and phenol added to the efficiency of the solution. He called attention to the fact that several different solutions have been called "Ochsner's solution," and for that reason the one he used was referred to as "modified Ochsner's solution." The solution accredited to Ochsner in some dictionaries would cause a slough in 48 hours, but the "modified Ochsner's solution" would never cause a slough in 48 hours.

Dr. Hayes believed that the reason this treatment had not become more popular was because the technic of applying it was not carefully adhered to, and that this was very essential in order to obtain the desired results. He said that the pack must be large, consisting of a thick layer of gauze over the skin, then a thick layer of good absorbent cotton, and an outside covering of rubber, making the whole dressing as nearly air-tight as possible. This dressing should not be disturbed for 48 hours except for the solution poured on two or three times a day through a small opening in the least dependent portion of the dressing. The solution Dr. Hayes now uses is: boric acid, saturated solution ounces 28, alcohol ounces 4, and phenol drams 1. The dressing must be kept thoroughly saturated with the solution.

Dr. Hayes called attention to the enthusiasm of some of those who have recently gone out from the University, over this method of treating these wounds, and their satisfaction in getting these patients back to work so much more rapidly than by other methods.

Dr. A. A. Zierold asked if Dr. Fowler's patient had gangrene before or after the application of the Ochsner's solution.

Dr. Hayes replied that there was a thrombosis present and evidence of a slough before the dressing was put on. This dressing will never give a slough in 48 hours.

Dr. Owen Wangensteen stated that Dr. Hayes may be perfectly right about the use of this solution. He called attention to the fact that when Dr. Hayes began injecting varicose veins others were amused over it but that it was now a universally practised procedure. He said that in the treatment of acute infections there are essentially two factors of primary importance: one is absolute rest, and the other increase of heat in the affected part. Nature does this in part by increasing the temperature locally. He wondered if water poured into the dressing as used by Dr. Hayes would not accomplish the same result, and called attention to the fact that a 1 per cent solution of phenol might cause gangrene in the terminal digits. However, he had seen patients treated by this method and had observed some of the good results which Dr. Hayes had obtained. He said he would like to see Dr. Hayes run a control series of these cases at the University Hospital, using hot water in the pack instead of the Ochsner's solution.

Dr. Hayes stated that no doubt the method of applying the dressing was an important factor and that fair results were obtained with boric acid or even with sterile water, but he had tried these many times. When the infection was severe this was not enough. After trying several solutions the one given above was found to be the most efficacious and, if properly applied, will not fail to localize any infection of the extremity in 48 hours. The suggestion of having some beds for this work in the hospital would be a most acceptable proposition.

Dr. William P. Herbst stated that it is an interesting fact that boric acid has been demonstrated in the urine 55 seconds after immersion of the foot in a tub of boric acid solution, even when the skin is unbroken. (Ref: Kahlenberg, L., Jour. Biol. Chem., 1924-25, lxii, 149, p. 405.)

(The patient was then shown and attention called to the location of the grafts and the excellent result obtained in this case.)

Dr. Thos. J. Kinsella of Glen Lake then read his inaugural thesis entitled "Phrenicotomy for Pulmonary Tuberculosis." This was illustrated with numerous lantern slides showing the condition of the lungs before and after operation.

An Eastman film on "Prostatic Hypertrophy" was shown after the reading of the papers. This proved to be an enjoyable feature of the scientific program and it is hoped that arrangements may be made to have similar films shown at future meetings of the Society.

The meeting adjourned.

H. O. McPheeters, M.D., *Secretary.*

PROCEEDINGS OF THE MINNEAPOLIS CLINICAL CLUB

Meeting of October 9, 1930

The regular meeting of the Minneapolis Clinical Club was held in the Hennepin County Medical Society Rooms, Thursday, October 9, 1930. Dinner was served at 6 o'clock and at 7 o'clock the business meeting was called to order by the president, Dr. Moses Barron. Minutes of the preceding meeting were read by the secretary and approved as read. After the regular business of the evening, the scientific program was given. It is as follows:

Dr. J. M. Lajoie read a paper on "Cardiac Emergencies" (to be published in Minnesota Medicine at a later date).

Dr. W. A. Fansler followed with a report of "Two Unusual Rectal Cases"; one of "Tuberculous Intestinal Fistula," and one of "Ischiorectal Abscess with Pneumonia."

The first case I wish to report is that of a female, married, thirty-two years old. Her history is unimportant except an operation for chronic appendicitis two years ago. Two months previous to my seeing her she began to complain of pain in the rectum and had an afternoon temperature of about 99.6. Complete physical examination with x-ray of chest, gastro-intestinal tract, blood examiantion and tuberculin reactions were negative. The only symptoms were a rapid pulse, about 110, slight afternoon elevation of temperature and nervousness. One month after the initial onset of symptoms a small mass about 4 cm. across was felt in the left rectal wall about two inches above the ano-rectal juncture. This was opened through the rectum but did not heal and was opened more widely ten days later. She did not improve and I was asked to see her two weeks after the second operation or two months after the onset of rectal pain.

Upon proctoscopic examination nothing could be seen externally. Internally an opening could be seen in the bowel wall about two inches above the ano-rectal junction above the insertion of the levator ani muscles. A probe revealed a cavity almost two inches deep and extending downwards along the bowel wall below the level of the opening of the abscess cavity with the rectum. The appearance of the lesion gave the impression that it was probably tuberculous. Under caudal anesthesia the opening was enlarged and carried down far enough so that adequate drainage from the lowest portion of the cavity was secured and all granulations were curetted out. These were examined by University pathologist and reported as being the product of simple chronic inflammation. The lesion still did not heal as rapidly as was desired and six weeks later a more radical procedure was done with the actual cautery. The tissue was again sent to the University and a report of chronic inflammation returned. Not satisfied with this report, the remaining tissue was sent to the Glen Lake Sanatorium, where serial sections were run and definite tubercle formation found. About this time I saw an out-of-town surgeon who had operated upon her two years previous and was told that at the time of operation he had found a tuberculous peritonitis with many miliary tubercles, the pelvis being especially involved. The patient was seen daily for almost nine months. The lesion was dressed daily and upon three occasions areas were cauterized at my office with the actual cautery. At the end of this time there was complete healing. It is quite possible that this fistula might have been healed more quickly if the incision had been carried down through both sphincters and well out into the ischiorectal fossa, thus converting the sinus into an open V-shaped cut. In doing this, however, sphincteric control would have been sacrificed and under the circumstances restoration of the sphincter by secondary operation might have been unusually difficult. I have cared for many cases of tuberculous fistulæ but I have never seen this type. To me it brought out two very interesting things: First, that a few microscopic sections, when negative, are of little value in the diagnosis of tuberculosis. In doubtful cases serial sections should be made. Second, it has again emphasized the value of the actual cautery in treating tuberculous lesions about the rectum. I use the cautery routinely in operating rectal fistulæ but its repeated use to encourage healing of sluggish areas, to me is new and the results encouraging.

The second case I wish to report is much more dramatic. I was called on the long distance phone and told that a patient was suffering from rectal pain and that he was being brought to Minneapolis that afternoon. Upon arrival his local physician gave the following history: The patient was a male, thirty-seven years old. His only previous history was that of an apical tuberculosis two years previously for which he was in a sanatorium for about three months. Since then his weight has been up and he has enjoyed good health. Two weeks previously he had injured his foot while playing golf, apparently an abrasion from his shoe. This was quite sore and a few days later he complained of pain in the rectum and some soreness in the right groin. His temperature was 101. Rectal examination revealed a tender spot just to the left of the prostate but no induration or swelling could be made out. He was kept quiet for a few days, the foot dressed and warm water enemas given. Under this he seemed to improve and returned to work. Three days later he called his local doctor at 2 a. m., because of the severe pain. The findings were the same as before except the pain in the rectum was so severe that one-fourth grain of morphine hypodermatically did not give complete relief and the temperature was again 101. Late that afternoon he was brought to me at Northwestern Hospital. When I saw him about 5 p. m., his temperature was 104.6, respirations were thirty and there was a slight degree of cyanosis. The glands in the right groin were palpable and tender. Rectal examination revealed a moderately tender area (on deep pressure) about 2 cm. in diameter and directly to the left of the upper portion of the prostate. No induration, fluctuation or other abnormality could be felt and the rectal mucosa over the tender area was normal in appearance. A blood culture was ordered. I felt certain that the symptoms were out of line with the rectal findings and asked for consultation. The leukocytes were 18,000, a moderate anemia present. *X*-ray of the chest showed a diffuse bronchial pneumonia. Blood culture revealed staphylococci and a gram-negative diplococcus in the blood stream. His condition became progressively worse and he died the morning of the fourth day after admission to the hospital.

Autopsy was obtained. The pleural cavity contained about 800 c.c. of cloudy yellowish fluid and many fresh fibrous adhesions. The pericardial sac contained fibrin threads in cloudy serous fluid. The heart was soft and flabby and contained multiple petechial hemorrhages.

The left lung showed old fibrous adhesions at the apex. Each lung showed similar findings. The pleura was covered with a thick fibrous membrane nodular in character. On section some of the nodules were seen to be infarcts; others were abscesses.

The left ischiorectal fossa contained an abscess the size of a small walnut and did not perforate the levator ani. A definite inflammatory process could be seen extending upward to the left inguinal region.

The diagnosis then was: (1) Ischiorectal abscess; (2) septicemia; (3) bronchopneumonia, bilateral with abscess formation; (4) cloudy swelling of the heart, liver, kidneys.

The history and antemortem findings in this case are to me interesting. In the first place it would seem that the original site of infection was in the foot. The second localized site where the infection struck was in the left ischiorectal fossa and inguinal glands, whether through the blood stream or lymphatics cannot be told. If through the lymphatics, then drainage of the ischiorectal fossa at the first onset of rectal symptoms might have been of benefit. At the time he was admitted to the hospital here I do not believe it would have been of value. The second interesting feature is the findings on rectal examination. The examination was absolutely negative except for the spot of tenderness. In every case I have examined previously there has been some induration or some difference in the consistency, size, shape or excursion between the normal and involved fossæ.

It is my custom to open every perirectal abscess the moment a diagnosis is made and in the past I have been able to make a diagnosis at once. In this case I was unable to tell whether an abscess was present or not and even had the patient's general condition been better I should not have felt justified in operating without further observation. This adds, then, one more point to our fund of knowledge. It may be possible to have a perirectal abscess without anatomical change demonstrable by palpation. Pain, tenderness and temperature alone may be enough to justify exploration.

DISCUSSION

Dr. LaVake: This case is very interesting to me. We find in gynecology that unless there is the definite indication for drainage—fluctuation—we almost invariably get into difficulty if we incise. Again and again in my early practice I would be overweighed by consultants in favor of draining an indurated area. In many instances I felt convinced that it spread the infection and in may instances the incision healed and fluctuation nearby required further incision. I believe this case was handled perfectly. The man likely had a positive blood culture when he was first seen.

Dr. McCartney: Dr. Fansler's point is well taken on the point of serial sections. I do not know whether it is always possible to run serial sections; however, it depends upon the size of the piece of tissue. Some little time ago we were asked to run serial sections on a whole kidney. We figured that it would cost $3,000.00 and a girl's time for a year to do this. It is perfectly true, too, that you may get the thing you are looking for in the first section, and then again you may not. We get pieces of tissue every now and again, where they are thinking of tumor, and yet multiple sections do not show any sign of the disease condition present in the piece submitted.

Dr. Fansler (closing): I do not believe that draining this abscess would have made any difference in the outcome. Possibly if I had seen him two or three days earlier, I might have felt justified in exploring the ischiorectal fossa. If I had seen him before his pulmonary symptoms developed and had drained the abscess, it is still a question in my mind as to whether it might have prevented the pneumonia for most likely the blood stream infection was already present.

In answer to Dr. Wynne's question as to whether a subcutaneous tuberculin test had been done. I questioned the doctor especially about this. I have seen a large number of tuberculous fistulæ, and I was suspicious about this one. He said he had done a tuberculin test, rayed the chest and had all other laboratory data and could not find a thing.

In answer to Dr. Barron's question as to whether the doctor had watched the patient over a period of time. He said he had observed and examined this patient repeatedly, including numerous rectal examinations. I may also add that this physician is a very careful, keen and competent clinician. I believe the infection probably originated in the pelvis. We do know that tuberculous abscesses are almost painless to touch unless complicated by pyogenic organisms. This one could easily have developed painlessly and was in the beginning deeply enough seated that it could not be palpated.

Dr. Donald McCarthy presented two cases, (1) "Malignant Hypertension," and (2) "Diabetes with Substernal Thyroid."

The meeting adjourned at 8:30 P. M.

Secretary.

Meeting of November 13, 1930

The regular monthly meeting of the Minneapolis Clinical Club was held on Thursday evening, November 13, 1930, in the Lounge of the Hennepin County Medical Society. Dinner was served at 6 o'clock and the meeting was called to order shortly after 7 o'clock by the President, Dr. Moses Barron.

There were 28 members and 2 visitors present.

Minutes of the October meeting were read and approved.

After a short business meeting, the scientific program was taken up as follows:

Dr. A. A. Zierold reported a case of "Sympathectomy as a Cure for Angina Pectoris," and after the reading of the history the patient was presented to the Society. The case report is as follows:

This patient is a man 60 years of age who has been suffering for three years from anginal attacks of increasing severity and frequency. He has been under the care and observation of an internist and the clinical diagnosis of angina pectoris has been confirmed by repeated electrocardiograms. During the past few months the pain has been sufficient to require large doses of morphin regularly. As the patient exhibited no evidence of cardiac decompensation it was thought that, could he be relieved of pain, he might be restored to some degree of activity and usefulness.

It was decided to attempt the alcohol injection of the cervical and thoracic sympathetic ganglia as advocated by Mixter and White. Because of the deep layer of fat and muscle overlying the upper thoracic spine the original technic could not be followed. Under novocain infiltration anesthesia a five-inch incision was made caudally from the level of the seventh cervical spine, parallel to and two inches distant from the upper dorsal spinous processes. The incision was carried through the muscles to the ribs, exposing them at the articulations with the transverse processes. Beginning with the first rib, a needle was introduced under the lower border at this point and directed medially and upward to reach the site of the sympathetic ganglion without entering the pleura. It was then aspirated to confirm its location, and a few c.c. of 1 per cent novocain was injected. Five needles were placed after this manner under the borders of the upper five ribs. In each of these 5 c.c. of 80 per cent alcohol were injected. The patient experienced no pain or discomfort, but noted an anesthesia of the inner side of the left arm and the left chest wall corresponding to the distribution of the upper five thoracic nerves. On the following day this was replaced by a similar area of hyperesthesia which gradually disappeared in the following two weeks.

The patient's convalescence was uneventful. The wound healed promptly and in a normal manner. It is now four weeks since his operation and he has not experienced a single anginal pain.

You will note that as evidence of the interruption of the splanchnic pathways, the patient has the enophthalmos and constricted pupil of a Horner's syndrome. The left hand is also warmer than the right as a result of vasoconstrictor loss.

It is yet too early to warrant any positive statement, but it appears reasonable to believe that the patient will be free from pain for some time, if not permanently.

DISCUSSION

Dr. H. L. Ulrich: I am sorry I did not know this patient was coming this evening and I would have looked over my notes before the meeting. I saw this man in consultation three years ago. He had a distinct coronary closure from which he recovered and went about his work again. This year I saw him again and at that time he was in a state of persistent anginal attacks. I suggested that he be operated on and that the thoracic ganglia be injected. This is as far as I am acquainted with the patient. At the time I saw him first he had distinct coronary disease and now gives evidence of conorary disease in the electrocardiogram. He is entirely free from pain.

Dr. Archie H. Beard: I understand that the results of this injection have the tendency to disappear, and that in time the attacks of angina are apt to return. I have the impression that White's last report stated that at the end of about three years some were having anginal attacks.

Do you think that this was due to faulty technic at the time of the injection, and do you know whether the same results occur when you cut down the ganglia and inject them direct?

Dr. Zierold: It is probable that the percentage of unsatisfactory cases is in direct proportion to those which do not develop a Horner's syndrome as secondary evidence of successful injection.

Dr. J. C. Michael: Do you attempt to expose the ganglia?

Dr. Zierold: No.

Dr. Michael: One would not, of course, expect a return of function in those sympathetics?

Dr. Zierold: I assume that the ganglia will be destroyed or irreparably injured by the alcohol.

Dr. J. S. McCartney read a paper on "Cirrhosis of the Liver," illustrating it with numerous lantern slides. (Paper to be published later, probably in the Archives of Internal Medicine.)

DISCUSSION

Dr. H. L. Ulrich: I merely wish to emphasize that clinically I have been struck by the fact that in adults about 40 years of age, or over, when you find a pleural effusion that you cannot explain, it is well to look at the liver to see whether or not that patient has cirrhosis. The pleura may be the first cavity to show fluid.

The liver is a strange field, a strange organ. In the last few years we are getting reports that by injecting a pigment into one group of portal veins it comes up in one lobe of the liver, and by injecting another group it shows up on the other side of the liver. This differentiation of the blood in the portal vein is very strange. That is just one of the little mysterious points about the liver. And these plates we have seen tonight are not made any clearer by such knowledge, but it merely shows why they may be so confusing.

Great credit is due to Dr. McCartney for his persistent attempt to bring clearness to this subject. We should be very grateful to him for bringing so much order out of an apparent chaos.

Dr. Barron: This is the type of paper that can bear a great deal of discussion both from the clinical and pathological standpoints.

Dr. Frederick H. Schaaf gave a talk on "Hunting Big Game with a Movie Camera," and showed two reels of pictures taken on his recent hunting trip in Canada. This was a very enjoyable addition to the program.

The meeting adjourned.

H. Bright Dornblaser, M.D.,
Secretary.

NEW AND NON-OFFICIAL REMEDIES

The Council of Pharmacy has accepted the following articles:

Abbott Laboratories
- Gold Sodium Thiosulphate-Abbott

Eli Lilly & Co.
- Erysipelas Antistreptococcic Serum-Lilly (Concentrated Globulin)

Medical Arts Laboratory, Inc.
- Antirabic Vaccine, Semple Method

National Drug Co.
- Antipneumococcic Serum, Type I
- Ointment Scarlet Red Biebrich 8 Per Cent
- Typhoid-Paratyphoid A Vaccine

Parke, Davis & Co.
- Ventriculin

Richards Pharmacal Co., Inc.
- Richards Psyllium Seed

E. R. Squibb & Sons
- Diphtheria Toxoid-Squibb, twenty 1 c.c. ampule packages
- Diphtheria Toxoid-Squibb, two 1 c.c. ampule packages
- Normal Horse Serum, one 50 c.c. vial package
- Ragweed Pollen Allergen Solution-Squibb (3 vial treatment package)
- Timothy Pollen Allergen Solution-Squibb (3 vial treatment package)

TRUTH ABOUT MEDICINES

The following products have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association for inclusion in New and Non-official Remedies:

McKesson's Vitamin Concentrate of Cod Liver Oil.—A cod liver oil concentrate having not less than eleven times the minimum Vitamin A potency of cod liver oil, U.S.P., and not less than eleven times the Vitamin D potency of a potent cod liver oil used as a standard. The product possesses properties similar to those of cod liver oil so far as these depend on the fat-soluble vitamin content of the latter. McKesson and Robbins, Inc., Bridgeport, Conn. (Jour. A. M. A., November 1, 1930, p. 1347.)

Maltine with Cod Liver Oil and Iron Iodide.—This product is composed of maltine, 70 per cent; cod liver oil, 30 per cent; and ferrous iodide, 0.44 Gm. per hundred c.c. (2 grains to each fluid ounce). Maltine is a preparation essentially similar to extract of malt, U.S.P., but it contains 3.8 per cent of alcohol, is prepared from malted barley, oats and wheat; its Vitamin B_1 and B_2 content and its starch converting power are controlled by assay. Maltine with cod liver oil and iron iodide contains in 100 c.c. from 23,000 to 25,000 Vitamin A units as determined by the U. S. Pharmacopeia assay and its Vitamin D potency is controlled by assay. Maltine Company, Brooklyn, N. Y.

Diphtheria Toxoid.—A diphtheria toxoid (New and

Non-official Remedies, 1930, p. 364), prepared from diphtheria toxin of which the L+ dose is 0.2 c.c. or less. The toxin is treated with formaldehyde and is tested for antigenic power. The finished product is adjusted to contain in 2 c.c. enough of the toxoid for one immunization treatment. It is marketed in packages of one immunization treatment. Lederle Laboratories, Inc., Pearl River, N. Y. (Jour. A. M. A., November 15, 1930, p. 1505).

Ampoule Sterile Solution Dextrose, U.S.P., 5 Gm., 10 c.c.—Each ampule contains dextrose, U.S.P., 5 Gm., in distilled water to make 10 c.c. E. S. Miller Laboratories, Inc., Los Angeles.

Ampoule Sterile Solution Dextrose, U.S.P., 10 Gm., 20 c.c.—Each ampule contains dextrose, U.S.P., 10 Gm., in distilled water to make 20 c.c. E. S. Miller Laboratories, Inc., Los Angeles.

Ampoule Sterile Solution Dextrose, U.S.P., 25 Gm., 50 c.c.—Each ampule contains dextrose, U.S.P., 25 Gm., in distilled water to make 50 c.c. E. S. Miller Laboratories, Inc., Los Angeles.

Dextrose (d-Glucose) Unbuffered and Without Preservative, 10 Gm., 20 c.c. Ampule.—Each ampule contains dextrose, U.S.P., 10 Gm., in distilled water to make 20 c.c. H. K. Mulford Co., Philadelphia.

Dextrose (d-Glucose) Unbuffered and Without Preservative, 25 Gm., 50 c.c. Ampule.—Each ampule contains dextrose, U.S.P., 25 Gm., in distilled water to make 50 c.c.; accompanied by an ampule of 2 c.c. of a buffer solution. H. K. Mulford Co., Philadelphia.

Dextrose (d-Glucose) Unbuffered and Without Preservative, 25 Gm., 50 c.c. Double End Vial.—Each double end vial contains dextrose, U.S.P., 25 Gm., in distilled water to make 50 c.c.; accompanied by an ampule of 2 c.c. of a buffer solution. H. K. Mulford Co., Philadelphia.

Dextrose (d-Glucose) Unbuffered and Without Preservative, 50 Gm., 100 c.c. Ampule.—Each ampule contains dextrose, U.S.P., 50 Gm., in distilled water to make 100 c.c.; accompanied by an ampule of 4 c.c. of a buffer solution. H. K. Mulford Co., Philadelphia.

Ventriculin.—Desiccated, defatted, hog stomach.—It is assayed clinically by observation of the reticulocyte response, the standard being an increase of red blood cells at the rate of about one hundred thousand cells per cubic millimeter per week when the product is administered to patients suffering from pernicious anemia. Stomach tissue of animals has been shown to contain a principle capable of stimulating the bone marrow to form immature red cells in large numbers. When, during the first ten to fifteen days treatment with ventriculin, a satisfactory rise in reticulocytes occurs, this is evidence that effective and progressive blood regeneration is taking place. Ventriculin is supplied in the form of a powder in vials containing 10 Gm. Parke, Davis & Co., Detroit. (Jour. A. M. A., November 22, 1930, p. 1589.)

Synephrin—Hydroxyphenylmethylaminoethanol Hydrochloride.—The hydrochloride of an alkaloid obtained synthetically. Synephrin is used as a vasoconstrictor. It is less toxic than either epinephrine or ephedrine, and its vasoconstrictor action, while not so pronounced as that of epinephrine, endures for a longer time. In combination with procaine hydrochloride it is useful for local anesthesia in dental operations and in minor surgery in cases in which a bloodless area is not required. The drug is also supplied in the form of Synephrin Solution "A," Ampoules Synephrin-Procaine, 3 c.c., and Hypodermic Tablets Synephrin-Procaine. Frederick Stearns & Co., Detroit.

Mead's Dextri-Maltose with Vitamin B.—A mixture containing approximately: maltose, 52.58 per cent; dextrine, 39.80 per cent; protein, 4.34 per cent; mineral salts, 2.28 per cent; and moisture, 1.00 per cent. It is standardized physiologically to contain in each 2.5 Gm. the Vitamin B_1 and B_2 equivalent of approximately 1 Gm. of dried yeast or 2 Gm. of wheat embryo. Mead's Dextri-Maltose with Vitamin B is proposed for use in the diet of infants suffering from Vitamin B deficiency. Mead Johnson & Co., Evansville, Ind. (Jour. A. M. A., May 3, 1930, p. 1405.)

Scillaren.—A mixture of the natural glucosides, scillaren-A and scillaren-B, occurring in fresh squill *Urginea maritima,* in the proportions in which they exist in the fresh crude drug; namely, about 2 parts of scillaren-A to 1 part of scillaren-B. Completely dried scillaren contains approximately 98 per cent of the active glucosides. Scillaren dried in a high vacuum at 78° C. for fifteen hours loses not more than 6 per cent of its weight. The cardiac action of scillaren is essentially similar to that of digitalis; but this action is apparently less persistent than that of digitalis. Scillaren is administered orally and is supplied in the form of tablets containing 0.8 mg. (1/80 grain) of scillaren and in the form of a solution containing 0.8 mg. (1/80 grain) of scillaren. Sandoz Chemical Works, Inc., New York.

Parke, Davis & Company's Codliver Oil with Viosterol 5 D.—A brand of codliver oil with viosterol 5 D.-N.N.R. (New and Non-official Remedies, 1930, p. 257). Parke, Davis & Co., Detroit. (Jour. A. M. A., May 31, 1930, p. 1761.)

CONSULTATION BUREAU

(Continued from page 92)

Answer.—If abortion is inevitable and there are strong pains without bleeding, the patient should be put to bed and nature allowed to take its course. If there is no possibility of avoiding the termination of pregnancy, and you are absolutely sure about this, and the process is lagging, stimulation of the uterus with quinine or pituitrin is indicated. If the patient is bleeding profusely a sterile pack may be inserted and removed before twelve hours. If the bleeding is excessive and cannot be controlled by a pack, the cervix should be dilated with a sponge forceps. In any event the patient should be kept in bed from five to seven days after delivery to allow involution to take place. Curettage should never be done even if the patient continues to bleed and material is present in the uterus until she has been free of fever for ten days and has a normal leukocyte count. If the patient is still having trouble (bleeding) and has been free of fever for ten days and has a normal leukocyte count, then a sponge forceps (sterile) should be introduced into the uterus with great precaution to avoid infection, and anything which is loose should be gently taken out.

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

EYE, EAR, NOSE AND THROAT

ORAL INFECTIONS AND THEIR RELATION TO DISEASES OF THE EYE: Henry Dunning (Arch. Ophthal., Sept., 1930, p. 315). Intestinal bacteria have a predilection for the pulp of teeth in which vitality is low. They find their way to the pulp of the teeth through the blood stream and cause the death of the teeth by their action.

Teeth become infected most often in the following three ways: (1) By the intradental route, in which the decay involves the pulp, then thepulp canal and goes onward through the apex of the tooth. This causes the true apical infection. (2) By the peridental route under the gingivæ, in which the peridental attachment into the alveolus is stripped up, thereby allowing bacteria to gain access to the bone. (3) Through the blood stream.

Pus under pressure, locked in a spongy vascular bone, gives no trouble for years, but continuously and relentlessly breaks down the patient's resistance until the chemistry of the body has undergone certain changes. Secondary changes then take place in the blood and perhaps all other tissues, including the eye.

For culturing organisms the tooth must be extracted under local anesthesia, as general anesthesia allows the socket to become contaminated with the increased flow of saliva and increased bleeding of the adjacent parts.

The question of pulpless teeth has not been settled as yet by the dental profession although the prevailing opinion is that nearly all pulpless teeth are infected and that most of them can not be made safe for the patients who are carrying them. Most pulpless teeth ought to be removed in a patient of about 50 years of age in order to reduce to a minimum the number of virulent bacteria, with their toxins, which are present in the body, just as it is a correct procedure to cut down to a minimum the number of bacteria in the milk or other food that one is to consume.

Furthermore it is poor practice to curet infected alveoli of teeth after extraction as it has taken many months to build up a barrier around the tooth and this should not be broken down, allowing the organism at the apex of the tooth to have free access into the walls of the newly formed wound. It is possible by this procedure to let loose into the system many dangerous bacteria and their toxins.

Carefully observed cases of orbital abscess, iritis, and uveitis that can be definitely ascribed to dental sepsis, have been recognized and described. While the exact process of extension is not known, yet the improvement of these eye conditions following the correction of the disease of the teeth is sufficient evidence that a close relationship exists.

The mode of transmission is probably in one of these three ways:

(1) Direct extension through bone.

(2) Direct extension along the periosteum of the malar bone.

(3) Blood stream (the most important).

The literature and case reports repeat over and over the evidence that infections of the mouth play an important rôle in connection with ophthalmic disease.

GERALD M. KOEPCKE, M.D.

PEDIATRICS

DEFECT OF THE DICK TEST AND ITS REMEDY: T. Toyoda and Y. Futagi (Jour. Infect. Diseases, 46-196, March, 1930). Toyoda and Futagi conclude that the Dick toxin consists of two toxins one of which is heat-labile and the other is heat-stable. The heat-labile toxin, which they consider to cause the symptoms of scarlet fever in its early stage, contains no nitrogen, and is easily destroyed in one half hour at 80° C. This heat-labile component of the Dick toxin gives strongly positive cutaneous reactions in individuals who are not immune to scarlet fever, and never causes allergic reactions. The heat-stable toxin, on the contrary, is not destroyed in two hours at 100° C., and when employed in skin tests often produces allergic reactions in those immunized against scarlet fever, which may account for the failure of the studies of various investigators to coincide with one another. Toyoda and Futagi feel, therefore, that in performing Dick tests one should use only the pure heat-labile toxin, and that skin reaction to this toxin accurately indicates susceptibility or immunity to scarlet fever.

C. A. Stewart, M.D.

CHOREA: A. E. Vipond, M.D., Montreal (Arch. of Ped., October, 1930, Vol. XLVII, No. 10). Chorea is due to a toxemia of the brain and spinal cord. This produces an irritability of the higher centers, including the intellectual centers, the cortical centers, the nuclei, which control voluntary movements, including the corpus of Luys, the red nucleus, the substantia nigra, and the lenticular nucleus.

It is pleasant to see all of the symptoms disappear under the sterilized milk treatment. He believes that this form of treatment is the best method of treating chorea in children. Method of injecting the sterilized milk: In injecting the milk, use a fair sized needle, as a small one will get blocked; inject five c.c. of sterilized milk every three days. Some patients will only require four to five injections, while others, mild cases, may require 18 to 20 injections to effect a cure.

How is it that sterilized milk injections effect a cure in chorea? Within one hour's time after the injection, the W. B. C. increase to an astonishing number. From the normal 8,000 we get an increase of from 11,000 to over 24,000, 16,000 being a common number. They prevent toxemia and then a cure takes place. They likely do away with the micro-organisms which produce these toxins.

The control centers, the intellectual centers and the mid-brain centers regain their tone and the patient's nervous system runs in a normal groove again.

R. N. Andrews, M.D.

SUSPECTED JUVENILE TUBERCULOSIS: Frederick Eberson, Ph.D., M.D., Jessie P. Delprat, M.D., and Ernst Wolff, M.D., San Francisco (Amer. Jour. of Diseases of Children, October, 1930, Vol. 40, No. 4). The symptoms that occurred the great number of times in both groups (group 1, giving positive tuberculosis, and group 2, negative) were cough, nervousness, fatigue, and lack of appetite. It was found that in group 1, 11.2 per cent, and in group 2, 12 per cent presented no clinical observations in regard to tuberculosis. This study has brought out the important fact that there was little or no difference between a group with positive and a group with negative tuberculin reactions, as judged by nine symptoms and ten clinical signs under consideration.

Two groups of children were selected on the basis of their reaction to tuberculin. It was found that in the positive group (206 patients), 36.4 per cent presented no symptoms, as compared with 42 per cent among the negative reactors (100 patients).

The differences between the percentages of total occurrences of symptoms in both groups were never greater than 7 per cent, except in the case of cough, which in the series of persons with negative reactions exceeded those with positive reactions by 13.4 per cent.

In the positive group, malnutrition, dullness of the manubrium sterni, and enlargement of the cervical lymph nodes, occurred more often; while D'Espine's sign, paravertebral dullness, and auscultation exceeded among those with negative reactions. It was found that in the positive group 5.8 per cent, and in the negative group 15 per cent presented no roentgen evidence. In the positive group, hilus calcifications, increased bronchial markings, and thickened interlobar pleura, occurred more frequently; in the negative group, peribronchial infiltration occurred more often. Observations that have been considered in the past as pathognomonic of tuberculosis were associated with nontuberculous processes in the lung. Such roentgen evidence, occurring alone, appeared to have no diagnostic value.

Evidence that has been presented in this study showed that commonly accepted clinical symptoms and signs have no diagnostic significance unless these are definitely correlated with positive tuberculin tests and roentgen observations that are positive for tuberculosis.

In terms of these more modern concepts an explanation has been found for the infrequent pathologic evidence of tuberculosis at autopsy as compared with the diagnoses on the basis of *x*-ray films of the chest.

R. N. Andrews, M.D.

THE USE OF POWDERED MILK AND MILK DERIVATIVES IN THE CONCENTRATION OF INFANT FOODS: Arthur F. Abt, M.D., Chicago, Ill., and Benjamin F. Feingold, M.D., Glencoe, Ill. (Arch. of Ped., October, 1930, Vol. XLVII, No. 10). Nearly all underweight and also many normal weight infants have a much greater nutritional requirement than the 40-50 calories per pound of weight which is considered the average normal need. In the premature, the feeble new-born, the poor nurser, or in all infants whose capacity is so limited that the average 24-hour food requirement can not be met by the usual formulæ, it becomes imperative to concentrate the feeding. It is a too prevalent theory that dystrophic infants must be fed on dilute mixtures.

One of the first methods for concentrating infant formulæ was the addition of cream. Later cereal foodstuffs were combined with the mixtures. Malt soups and butter-flour mixtures were employed. More recently stronger milk mixtures (⅔ or ¾ milk) have been used. Concentrated protein milk and finally whole milk with very high percentages of carbohydrate, such as Schick's Dubo with 17 per cent sugar, have been advised. Unless the infant receiving a high carbohydrate formula was kept under closest observation, diarrhea easily developed. The author has found that the simple addition of powdered milk and milk derivatives can solve the problem of concentrating formulæ in a very practical and satisfactory manner.

The author has used calcium caseinate for breast-fed infants developing diarrhea. In these cases the calcium caseinate is added to water in the proportion of one level tablespoonful of the powder to three ounces of water. Occasionally we encounter a new-born infant with small, frothy stools accompanied by a progressive gain in weight. By preceding the breast feeding with one ounce of powdered protein milk mixture and limiting the time at breast to 10 minutes, we have been able to check the frequency of stools and readily clear up the sore buttocks. With prematures having normal stools, the addition to one to two drams of condensed milk to the whole day's feeding of breast milk will sufficiently increase the caloric intake to produce a progressive rise in the weight curve. Very often a normal child is encountered, who is not contented with the caloric intake offered by a formulæ prescribing such a volume, while on the other hand the baby is unable to care for a larger amount. In such instances, add condensed milk or powdered whole milk. The powdered milks and their derivatives also find a very useful rôle in the treatment of vomiting in infancy and childhood.

ROENTGENOLOGY

THE IRRITABLE COLON: John Muir, M.B. (Brit. Jour. of Rad., III, 33, Sept., 1930, p. 391). Many vague dyspeptic symptoms are associated with colonic disorders in which treatment of the direct gastric symptoms has proved only palliative. The author calls this relationship the "radiological symptoms complex," and it is present in cases in which the duodenum shows signs of irritation which may be due to local ulcer but no direct evidence of such ulcer is detected and the appearance may be due to reflex irritation as from a pathological gallbladder, appendix or colon. This relationship to pathological gallbladder and appendix has been noted frequently.

The irritable colon is the third relationship and these cases are marked by spasm of the pyloric vestibule, pyloris, and duodenal bulb of varying severity and location. There is tenderness on palpation over the colon often accentuated over the middle of the transverse colon where the site of its origin may be mistaken as being in the lower pole of the stomach, or at other times at its maximum over the descending colon. The irritable colon shows exaggerated and irregular segmentation or haustration eighteen to twenty-four hours after the opaque meal. At times there is also a definite narrowing without segmentation especially in the splenic flexure and descending colon which is generally better shown by the opaque enema. Here the radioscopic observation is very essential. The most information is obtained by a combination of the opaque meal and enema. The condition can generally be differentiated without difficulty from an organic infiltration by the permanency of the defect in the latter.

Some cases present localizing symptoms such as indefinite backache, cramp-like abdominal pains which direct attention to the colon, chronic constipation or occasional or persistent diarrhea. Apart from these, the most common case is one which presents symptoms usually associated with or ascribed to duodenal ulcer.

In conculsion, the author says that this study is an endeavor to interpret function by radiological means.

Jacob Sagel, M.D.

THE PATHOLOGY OF EARLY PULMONARY TUBERCULOSIS AS REVEALED BY X-RAYS: Peter Kerley (Brit. Jour. of Rad., III, No. 33, Sept., 1930, p. 404). The author discusses the earliest tuberculous focus in regard to its anatomy, situation and mode of entry of the bacillus. According to *x*-ray appearance, there are three distinct types of infantile pulmonary tuberculosis: (1) tuberculous bronchopneumonia, (2) localized caseous pneumonia, (3) diffuse caseous pneumonia. All three types present a visible pulmonary lesion, and in about fifty per cent enlarged bronchial glands can also be demonstrated. *X*-ray evidence supports the view of Ghon, McCallum and Küss that the primary infantile lesion is pulmonary and not glandular. The development of the three types is traced and the *x*-ray appearance noted.

In adults, the infraclavicular region is the commonest location, the right side being more frequent than the left. In 1922, Assman described a round sharply defined opacity in the right subclavicular region which he called a primary tuberculous focus, and which he believed was a common method of occurrence of tuberculosis. Two such case at autopsy showed a localized caseous pneumonia deep in the middle of the upper lobe where no physical signs would be possible. The lesion is identical in infants and adults, and differs only in location. For mechanical reasons, the base of the lung is attacked in children and the upper lobe in adults.

The prognosis in early cases depends largely on the inherent resistance of the patient, and also on the site of the lesion. With reasonable care most infants cure themselves. The early adult focus may heal by resorption or by calcification and fibrosis. The constant situation of the lesion in the infraclavicular region points more to reinfection rather than a recrudescence of an old infection. Large caseous pneumonias in adults are very dangerous, and tend to end fatally in a short time. This lesion is the "galloping consumption" of the last century.

A triangular caseous pneumonia in an adult appears to spread and break down more quickly than the round caseous pneumonia of Assman. Pure apical tuberculosis tends to heal spontaneously, and the prognosis is always good. This has been proved by Fishberg in a large series of cases.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

Mental Aspects of Stammering. C. S. Bluemel, M.A., M.D., L.R.C.P. (Lond.), M.R.D.S. (Eng.). Clinical Instructor in Neurology of Colorado School of Medicine, etc. Illus. 152 pages. Price, $2.50. Baltimore, Md.: The Williams & Wilkins Company.

EDWARD JENNER AND THE DISCOVERY OF SMALLPOX VACCINATION.

Louis H. Roddis, M.D. 155 pages. Price $1.00. Banta Publishing Company, 1930.

This interesting little volume will afford an enjoyable evening's reading to any one. It includes references to the prevalence of smallpox in the earliest historical records, and describes the development of inoculation with smallpox. This practice, designed to infect susceptible individuals with mild smallpox, was practiced in the Orient during the seventeenth and eighteenth centuries. This measure operated with considerable success, although occasionally fatal cases developed in inoculated persons; yet it was infinitely preferable to the malignant smallpox, epidemics of which ravaged Europe frequently. Inoculation with human smallpox was popularized in Europe early in the eighteenth century by Lady Mary Montague, who observed the practice in Constantinople. She writes in the skeptical vein adopted by quacks of the present era: "I am patriot enough to take pains to bring this useful invention into fashion in England; and I shall not fail to write to some of our doctors very particularly about it, if I knew any one of them had virtue enough to destroy such a considerable branch of their revenue for the good of mankind."

In America, inoculation was warmly urged by Benjamin Franklin, and through his influence it attained considerable vogue.

Jenner's life is pictured in a readable manner. His medical career began at the age of thirteen, as a surgeon's apprentice. In his twentieth year he became a house pupil of the renowned surgeon and anatomist, John Hunter, and two years later took up rural practice in Gloucestershire. Jenner's broad interests in biology and natural history caused him to investigate thoroughly the common belief among the laity that infection with cowpox, such as frequently occurred among dairy-hands, invariably made them immune to smallpox. His memorable application of this fact in scientific manner, and his demonstration of the result by deliberately exposing those vaccinated to smallpox later, without infection developing, won immediate recognition in England, and imperishable fame to Jenner. In but a few years vaccination was practiced generally over the civilized world. In 1799 it was introduced in America by Dr. Benjamin Waterhouse of Boston, who obtained virus from Jenner, and vaccinated his own seven children. Later he tested its efficacy by exposing three of them to smallpox, with no ill effects.

Jenner's versatility and wide interests manifested themselves by his researches in biology and ornithology; he was a poet of no mean caliber, and a keen student of human nature. The latter quality reveals itself in the following passage, taken from a letter wherein he comments on the fact that the boyish appearance of his capable assistant interfered with his gaining the confidence of his patients: "For it is by appearance, not from real knowledge of things, that the world (at least a major part of it) forms a judgment. A look of significance, a peculiar habit, and a very scanty acquaintance with the human machine, will make a man pass current for a great physician."

Thomas Myers, M.D.

ALIMENTARY ANAPHYLAXIS (gastro-intestinal food allergy).

Guy Laroche, Charles Richet and François Saint-Girons. 139 pages. Trans. by Mildred P. Rowe and Albert H. Rowe. Berkeley, Calif., Univ. of Calif. pr., 1930.

This is a small monograph which was written first in 1920 in support of an argument at that time little held, *i.e.*, the occurrence of sensibility and anaphylaxis from alimentary absorption of foreign proteins. It has been translated into English and reprinted with footnotes by the authors written this year from the knowledge gained in the last ten years. While the information contained is now more or less commonplace, this volume is worth reading partly as a summary of the knowledge of alimentary anaphylaxis, and partly to see the progress of ten years. There is much left out, of course, but an evening spent on "Alimentary Anaphylaxis" will be well spent.

H. B. Sweetser, Jr., M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of **Commerce.**

PHYSICIAN'S OFFICE FOR RENT—Best location Midway district, corner Thomas and Hamline, Saint Paul. Rent $25.00 a month. Inquire at dentist's office.

WANTED—Resident physician. Salary and maintenance. Good opportunity for surgical experience. For particulars see A. G. Stasel, Superintendent Eitel Hospital, Minneapolis.

MINNESOTA MEDICINE

Journal of the Minnesota State Medical Association, Southern Minnesota Medical Association, Northern Minnesota Medical Association, Minnesota Academy of Medicine and Minneapolis Surgical Society.

VOL. XIV February, 1931 No. 2

THE PLACE OF THE LOCAL MEDICAL SOCIETY*

William J. Burns, LL.B.,
Executive Secretary of the Wayne County Medical Society
Detroit, Michigan

YOUR Program Committee has been very kind in inviting me to Minnesota to give you a few slants upon the work and problems of the county medical society and upon some exceptional activities and pioneering steps which are bound to exert a growing influence upon every individual medical society in the country.

Every county should have its medical society and to insure success in all its undertakings, there should be but one and only one unit. In the larger cities special groups may be organized, such as a Medical Section, or a Surgical Section, but for the sake of complete harmony and permanent good to the local profession and to the public, each and every medical group should be an integral part of the parent medical society.

Among the modern functions which are being sponsored by progressive county medical societies in the United States may be listed: (1) *Definite organization* along economic and administrative lines such as has proven successful in the business world; (2) *A program of education and service* to the profession and to the public, which includes daily or weekly newspaper columns, speakers' bureaus, physicians' telephone exchanges and collection and credit bureaus, etc.; and (3) a very satisfactory *courtesy program*, which includes coöperation with the judiciary, and close contacts with business leaders, civic officials, legislators and other office-holders.

DEFINITE ORGANIZATION

Realizing that the county medical society must be the center of medical activity in the community, officers of many such units in the United States are reorganizing their societies along business lines and placing the administration of the association's affairs in the hands of a full time employee. The Society's importance to the community is too great to hazard it by a careless or indifferent attitude. Outside interests have already attempted to lessen the influence of the county medical society. Now is the time to step in and by positive activity save the situation before it is too late. Better business administration would mean better programs, larger attendance, greater influence and enhanced prestige to the whole profession, with resulting benefits to the individual practitioner. Members of smaller county societies know the advantages of joint meetings with neighboring societies, for example, the enthusiasm and benefits of a tri-county meeting. The day must come when not only will every larger society have a definite program along economic lines, but the smaller counties will unite in groups of three, four, five or six societies, outline a coöperative plan of progress and employ a full-time individual to execute the business details. Good results must follow. This plan is to the interests of the individual practitioner of medicine.

A BULLETIN

Wherever possible, county medical societies should publish a bulletin. It is one way to keep up the interest of the membership, and to tell the world what the local medical profession is doing for the community good. In addition, a bulletin in the hands of a live business manager can be a source of revenue, as many manufacturers are glad of an opportunity to use the medical man's publication to advertise their products. The mailing list of a medical "house organ" can include the names of physicians in neighboring cities and also prominent laymen, and can be the means of increasing the prestige of the medical men who publish it.

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 14, 1930.

PROGRAM OF EDUCATION

The movement of popular medicine had its origin some years ago, and, through the stimulation of the American Medical Association, has developed from small beginnings until it has become a very influential organization in some county medical societies of the United States.

EDUCATION COMMITTEE WORK

In Toledo, Ohio, it was my privilege to see an educational program launched and developed. For years back, several of the more foresighted members of this county medical society realized the value of a program of popular medical education. It remained simply to put it into being. Numerous meetings were held over the luncheon table to discuss ways and means. At one notable meeting back in 1924, the officers of the society decided finally that problems dealing with clinic abuse, contract practice, unethical conduct, fraudulent advertising, quackery, misinformation of the public on matters of health, and a host of other things could be best met by broadcasting first hand the doctors' viewpoint on these medical matters, rather than the laymen's. This was a departure from the old notion of keeping silence on such matters from a mistaken idea of "ethics." This position is hardly tenable. The distinction has well been made between "advertising," which is closed to the physician as an individual, and "publicity," which is open to the profession as a whole. Not all the members, however, were sold on the soundness of the idea. You gentlemen probably will encounter the same condition in your own ranks; yet it is clear that your responsibility as guardians of the public health demands that you take more than a passive interest in such matters. In addition, your acceptance of this obligation will result in increasing your financial as well as your scientific revenue.

The officers of the Toledo Academy decided definitely on the necessity of forming an Education Committee to look after these matters in point. Such a committee would bring about a better relation between the public and the profession, which would be of advantage to both.

DAILY NEWSPAPER COLUMN

The beginning of popular medical education in Toledo was made early in 1926 with weekly health articles in two of the leading papers. The committee's plans were visionary. It had no precedent to follow. Few realized its possibilities. The first year was spent mainly in building up experiences and gaining contacts. It can truthfully be said that it sold the idea of honest guidance and authentic information in medical matters to the newspapers and the public. This was a worth-while accomplishment. But the committee quickly realized that the infrequency of appearance of its articles would lose force. Plans were set afoot to publish a daily medical article. This was a radical innovation in newspaper circles. True it is that daily newspaper medical articles had appeared previously in syndicated form. These, however, reflected only individual opinion in medicine. The "Said by Toledo Doctors" column, with its daily article, attempted to reflect the accepted opinion of the bulk of the medical profession. In this respect, it pioneered.

On February 27, 1927, the new column was inaugurated. During the next two years, a daily article was printed, followed by a "Question Box." Society members submitted articles to the Publications Bureau, which revised and edited them to fit into the program. Names of physicians were not signed to the articles. Self-diagnosis and self-medication were discouraged. The motto throughout was: "See your doctor first."

SPEAKERS' BUREAU

Realizing that the Speakers' Bureau was a necessary adjunct to the work of the Publications Bureau, this department was formed in 1927. For the first half year it worked sporadically. But the profession realized that the Speakers' Bureau was a powerful and valuable arm in bringing the medical man in direct contact with the public, so a concerted effort was made to boom this feature. The result was that during 1928 and 1929 the Speakers' Bureau sent out an average of ten lecturers each month to address lay organizations, civic clubs, etc. The public seemed to be hungry for information dealing with its health. These two departments, the Publications Bureau and the Speakers' Bureau, had a far-reaching effect. In Toledo, they did more than all the preaching in the world to counteract the propaganda of the quack and the pseudo-medical man. They established the doctor in the hearts of the people. More important, they made patients proud of their own doctor, and resulted in building up that confidence which is so necessary in the successful care of a patient.

With a full time secretary, any county medical society or group of societies could establish a Speakers' Bureau, and institute a weekly or more frequent newspaper column, with far-reaching and beneficial effects to the organization and its members.

PROGRAM OF SERVICE

A modern county medical society cannot do full justice to its members and to the public by a program of education alone. It must augment it with a program of service. A collection and credit bureau and a physicians' telephone exchange are two good items in a program of service. In competent hands, both can be profit-making activities. Here is a brief consideration of each plan.

CREDITS AND COLLECTIONS

For years, the Wayne County Medical Society of Detroit has successfully maintained a physicians' business bureau. For obvious reasons, this bureau uses a different name than that of the society and has its own corporate entity; however, it is controlled by a committee of physicians from the Society.

It offers three distinct services to every individual member of the Society: first, credit ratings on every person who visits the doctor's office can be obtained, in case a physician doubts the paying ability or paying inclination of his patient; second, the Delinquent Account Letter Service can be used whereby a series of letters is mailed by the Bureau to slow-pay patients to aid the doctor's collections; third, the collection division offers its dependable help to the physician who wishes to have his older accounts adjusted or financed.

Annually, the Bureau sponsors a lecture course on "Economics." These talks, given by prominent laymen who are specialists in their fields, are presented at the regular weekly meetings of the Society during one particular month. Physicians, their office secretaries, bookkeepers, workers in hospital offices, and all others interested in the business side of a doctor's practice are invited. This year the subjects of the lectures were: "Systematizing the Office Records" given by D. J. Terpeney, Dean of the School of Commerce, Detroit; "Credit Information," by Lee S. Carrick, Service Director of an industrial bank of Detroit; "Suggested Aids in the Collection of Accounts by Physicians," by Grahame Coffee, Collection Manager of Detroit's largest department store; and "Two Prescriptions: (1) Better Coöperation Betwixt You and Us; (2) Investment Buying by Doctors," by Kenneth Barnard, Manager of the Better Business Bureau of Detroit.

Along similar lines, another activity of a county medical society can be the publication of a "Confidential List for Members Only." This confidential list, added to monthly, contains the names of people with whom the society members have experienced unsatisfactory financial relations. (This is sometimes referred to as the "Deadbeat" list and of course is in code, to eliminate the possibility of law suits.) A copy of this list is mailed to each member so that he may study it whenever a new and questionable patient appears in his office for service. A master-list should be kept in the office of the medical society.

PHYSICIANS' TELEPHONE EXCHANGE

A county medical society activity which is spreading across the country is the physicians' telephone exchange. In a certain midwest city, such a bureau has been running twenty-four hours per day since August 1, 1925. It was started with a campaign for members. Approximately 100 subscribers joined before operations were begun. This number increased gradually to 160 (close to 50 per cent of the active membership) and this is believed to be the saturation point. The subscribers are assessed $3.50 per month, payable quarterly, for this extra service. It is owned and controlled by the society, with the board of trustees acting as a supervising committee, but it is operated as a separate entity. The bureau is not incorporated but is classed as a department of the society, which is incorporated not for profit. The Doctors' Service Bureau has its own employees and its own system of bookkeeping; the bureau has nothing to do with the general funds of the county medical society. The main object of a physicians' service bureau is to be a connecting link between the doctor and his patients. Most of this bureau's work consists in patients calling for their family physician or making appointments with a specialist, which is desirable business. It gets a share of emergency calls but these are necessary evils. Often there is no remuneration to the doctor for such work. But such a bureau, being a quasi-public agency, must accept the good with the bad.

TELEPHONE EXTENSIONS

Fifty-five subscribers have installed direct telephone extensions from their offices or residences (or both) to the Doctors' Service Bureau offices. A special switchboard has been installed which combines main trunk lines and these extensions. Every time the telephone rings in the doctor's office or residence, a light signal is received in the bureau's office. If the doctor fails to answer, the message is taken until he returns. In this way, no business is lost by a subscriber with an extension. It is a boon to the younger man who cannot afford the expense of even an eight-hour office assistant, not to speak of twenty-four hour telephone coverage. The subscriber pays the telephone company a sum for this extension equal to the aerial distance from his office or residence to the bureau office.

The operation of a physicians' service bureau brings with it loads of grief. Just try to please everybody! But it is worth all the trouble. A bureau helps to pep up the society and makes it the center of medical activity in the city. It helps to unify the doctors, which seems to be a problem in every city, town and hamlet. The advantages seem to outweigh, by far, the troubles. The people come to the society headquarters for all medical and miscellaneous information, including opinions on quacks, and it is felt the bureau has been largely the cause of this decided advantage.

MEDICAL DEFENSE

Another valuable item in a program of service is medical defense against malpractice suits. In Michigan, two dollars of the dues sent to the State Society go to a Medical Defense Fund. It is interesting to note that in the city of Detroit, not one malpractice suit has been lost by a physician during the past three years. It pays to be organized.

The Wayne County Medical Society has luxurious club rooms, a cafe and a roof garden for the use of its members. Originally, it purchased a residence for $17,500 which, in the boom of 1926 was sold for $110,000. Bonds were purchased and plans for the erection or purchase of another "home" are now before the Board of Trustees. The present leased headquarters occupy the eleventh floor of a skyscraper facing the Art Center. The men especially enjoy the dining room feature of the society and gather every noon for good food, conversation and cards. All committee meetings are held at the headquarters over the luncheon table. The Cafe certainly helps good fellowship and *esprit de corps.*

A program of service in conjunction with social features is necessary for a county medical society if it hopes to achieve that place in the sun which brings tangible benefits to its individual members.

COURTESY PROGRAM

Physicians frequently learn of the illness of a medical confrère. They think of it momentarily and then forget it in the stress of making a call or getting to the office on time. Such a matter deserves more attention: for example, the mailing of a sick card, a daily telephone call for reports, a visit from a member of the welfare committee, and the insertion of the sick man's name in the Bulletin would not be amiss. When one person is responsible for the fulfillment of a courtesy program, it is carried out with infinite pains.

Last March 15th, a certain Ohio doctor (like thousands of other poor mortals) was making out his income tax report. He called his medical society office. Could he, he asked, take as a deduction the legal expense incurred in fighting a malpractice suit which had been inflicted upon him during the past year. He was made very happy in the knowledge that this was an allowable deduction and he took down the exact citation in order that there would be no question concerning his report when it reached the income tax office. This was another small item of service rendered by one charged with certain responsibilities of courtesy, resulting in greater good-will for the county medical society.

To protect its own and its members' interests, and to grow in influence and prestige, a county medical society must become active in civic affairs, and contact business leaders, legislators, judges and other officeholders.

CONTROL OF CLINICS

Recently, in a suburb of Detroit, an uplift association decided to promote a round-up of the pre-school child. This lay organization made all its plans without interviewing the representatives of the medical society. It decided that a school building would be the proper place for such a "demonstration." All basic plans for the examination of 1,000 children—a strictly medical gesture—were formed without a bit of advice from medical men. The laity, as usual, was making plans to run the doctor's business. Fancy a lay organization attempting to formulate plans to run any other business.

Physicians first learned of the program when they received a letter advising them of the hours and days they were expected to be present at the school house to perform the examinations. The invitation read: "The Clinic, as a part of the round-up for almost 1,000 children, will be held June 24th, 25th, July 1st, 8th and 10th from 9:00 A. M. to 12:00 Noon." Such a plan was so contrary to the ruling of the Wayne County Medical Society, which stated that all such examinations were to be made "in the offices of private physicians," that doctors in this suburb, members of the society, suggested to the officers of the association that a change in plans might be advisable. These physicians wished to coöperate in the campaign in the interests of better health. They found, however, that the round-up promoters were adamant. They would go through with their plans, they said, if it were necessary to import doctors from outside the city and the county. In fact, the first day's examination was held as scheduled and a few physicians, not members of the society, were present. The threat that imported doctors would be used bore no weight, as the Michigan State Medical Society heard of the plan and upheld the ruling of the county society. Doctors in other counties had no desire to step into a political trap. The better qualified physicians of the city were not present at the examinations, which to anxious parents were far from being a success.

That which should have occurred in the first place, before the inauguration of any plans, was the final result: a conference between officials of the lay association and the proper committee of the Wayne County Medical Society. This friendly get-together resulted in mutual understanding and the formulation of plans agreeable to the Wayne County Medical Society and in the best interests of real public health. In future, all medical plans in this suburb will be referred to the physicians at their instigation and not when completed. The children—future citizens of this suburb—will receive better attention from the physicians in their own offices. Thorough examinations will be given and all defects will be discovered. Better general health in the years to come will be the direct result.

Medical organization has again lived up to its unsefish principles of better public health as well as the protection and education of its members.

CONCLUSION

You have heard a few of the activities of a modern county medical society which employs an executive secretary to carry them out. Without a man responsible for these duties, the bulk of this work must be borne by some member of your society. A physician has not the time to give from his practice to a thorough handling of it. Some things must be glossed over and slipped. Perhaps those things of most concern to you may be in this number. In any case, admitting the doctor's full capability, and usually he is very capable (or he would not have been chosen for office by his confrères), it is not just to saddle detail work of this kind on his shoulders. More than that, it will mean a failure to progress along the modern lines of education, service and courtesy which you all desire. It becomes absolutely necessary to entrust such matters to one who can give to them his whole time and undivided attention. Let the policy of the organization be dictated by the officers; the details of its execution can be handled by a full-time man. Such a manager is styled an Executive Secretary. I have been told that the county medical societies throughout the country which have decided upon a modern program and have employed an executive secretary to insure its accomplishment seem to be outstanding. They tell me the program has been important to all in its relation to the actual scientific practice of medicine. Therefore, I may venture the prediction that every society of prominence will sponsor such a program and have an executive secretary in the very near future. The investment will pay rich returns, economically and professionally.

THE ECONOMIC TREND IN MEDICINE*

J. G. Crownhart, Secretary, State Medical Society of Wisconsin
Madison, Wisconsin

IN medical organization possibly few but officers appreciate so fully that the first aim must ever be the advancement of the scientific attainments of every member. Those who would fulfill their obligations as officers must never lose sight of this foremost purpose. As it is successfully advanced, experience demonstrates that many seemingly independent and difficult problems disappear.

On the other hand, without tinge of commercialism, organized medicine has a primal duty to perform in safeguarding and promoting the material welfare of its members, which is in no sense different from the welfare of the public. This can be performed without making the attainments incompatible with a higher type of public service, for, indeed, the two can only proceed hand in hand.

In the time allotted, I stress here only this seemingly materialistic side of organized effort. Almost unwillingly I am compelled to submerge some of the more humanitarian aspects and attainments. In the nine months just past, visiting the county medical societies of Wisconsin, we have been able to point out concretely how four comparatively small accomplishments of their State Society have saved every member $27.00 a year in perpetuity,—$17.00 a year more than their state dues. Computed on the basis of the bankers' investment table, this makes the certificate of membership worth almost $300.00 on these four items alone.

To this we have been able to add the recital of achievements,—measure after measure, project after project,—which have potential values running into many thousands of dollars, which we are not able to compute or allocate with definiteness to any given member. These projects have met with success because primarily they have been of public service. The physician does not profit on the income that sustains him, but only upon that usually thin top layer that spells laying away a competence for old age, making possible the education of his children and affording the enjoyments of well earned comforts. Within this narrow bracket organized medicine in Minnesota and Wisconsin has done much, and can do more, to promote the worthy ambitions of every member.

Some two years ago, however, the Council of the Wisconsin Society had a conscientious feeling that, while we had been able to accomplish very gratifying results, such attainments largely had been possible through the correction of existing injustices to members of the profession, particularly through relieving those injustices formerly to be found in the laws of the state. With this field of effort for the most part now obviated, the Council believes that a broader opportunity for service to the members and public alike lies in the adoption of a broader viewpoint,—the recognition of the value of statesmanship to guide the future of medicine and public health endeavor.

Today, as never before, they feel there is unfolding and developing with great rapidity a newer recognition and clearer appreciation of the value of good health and the cost of preventable disease. Legislatures, industries, insurance companies and school boards all are cognizant of the tremendous possibilities for health conservation which would be reflected in lower taxes and increased profits. As for the individual, something has happened that possibly no one could have foreseen a few years ago. From the precept of frugality, today man is besieged on every side by high pressure salesmanship to enjoy present comforts and luxuries by mortgaging his future income. Urged even by some banks to save only presently so to spend, the individual has brought home to him most vividly the fact that the so-called unexpected illness climaxing a mortgaged income may spell financial disaster. For such disaster the costs of medical care—the straw that broke his financial back—is burdened with all the blame.

Today, as at no time in the past, large numbers of people are ready to receive, frequently to seek, medical charity where they would never think of accepting, much less soliciting, charity in the way of food, fuel, light, clothing or shelter —other basic necessities.

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 14, 1930.

Added to these two factors, the Council is convinced that the ever present and age old desire of all mankind to leave a record of some useful and unselfish act for posterity to revere, is being translated more and more into terms of doing something for the public health. You can name to yourself twenty to thirty organizations in Minnesota that have such a purpose as their primary or secondary goal. The disturbing element is not the altogether fitting end in view, but the frequent pathetic attempts at proper translations through hasty or ill-advised legislation.

Josh Billings said some years ago, "It ain't ignorance that hurts people so much as it is knowing so many things that ain't so." The identical situation here exists. It is not that the layman and his organizations are insincerely interested in advancing individual and community health. Indeed they are most sincerely interested. But the real truth is that what will advance the public health is a highly technical subject. Physicians, like supervising architects, must draft the plans and closely supervise the construction if the building is to stand in storm and sun. Much must be accomplished through education which is almost as slow in results as the generations.

Now we find that new agencies have recently entered the field. Non-medical organizations and groups seek to hasten the end in view by group action and legislation. They undertake to become the architects and the engineers. The dangers to the public itself of such a diversification and diffusion of authority, however, are so apparent to you as trained technical advisors that you wonder why others fail to appreciate and recognize the hazards. This modern tendency for immediate action, this demand for speed, this impatience with time for winnowing and sifting, brings to the organized profession many of its present and most pressing problems.

Busy physicians cannot hope to find the time to meet as individuals these group problems. Simple questions may receive momentary solution but to chart the course which shall determine the policies, ambitions and lives of men in a great and forward looking profession requires consultation, consideration and research. Only through a unity of action, a devotion to high purpose, can organized men and minds find the broad way worthy of the past. In this effort there are no short cuts to a real and lasting success. But scientific organizations, by enlisting the support of all members, may well undertake to diagnose and treat the specialized needs of a whole people. Such an organization may well render a distinguished service to the public and members alike by the development of a statesmanship in medicine that will offer competent direction and forward looking policies further to enhance the value and extend the benefits of scientific medicine to a whole people.

Such efforts require funds which may only be secured immediately by increased dues. Every society, I care not what it may be, can only justify its dues upon at least dollar for dollar benefit and dividends to its members. Such returns, far exceeding the dues paid, long have been made manifest in Minnesota and Wisconsin. Money so spent in the purchase of profits is no luxury.

We will never have an appreciation of the probable costs of insufficient direction and action, so long as competent effort forestalls what would otherwise occur and the consequent assessments. So it is that the program of the future in direction and prevention may not bring such apparent returns. But just as you can justify the expenditure of money for prevention of typhoid, diphtheria and smallpox, so must each physician appreciate that the efforts of his state society and parent organization will also pay dividends far exceeding those of the past.

It has been my privilege to explain this situation to forty-four county medical societies in Wisconsin during the last few months. Neither advocating nor defending a proposed substantial increase in dues, it has been my sole purpose to outline in more detail the general propositions submitted to you this evening. Of forty-four voting, only one has voted against increasing the dues from $10 a year to those of Minnesota—$15 a year. Wisconsin, appreciating the foresight of your officers, is frankly following in your footsteps.

There will always be those who will say, "It can't be done." But if the program of Minnesota and Wisconsin meets fairly and squarely the needs of the great group of physicians, it cannot fail of accomplishments that will be valued by thoughtful members and welcomed by the public. Such accomplishments will far exceed those of the past even though they take years, instead of months, in the doing.

This is a world of progress. It is a day of changing problems; a time for new foresights. The dying and the dawning made by the advance must keep us ever alert to the ideals which the profession of medicine demands. More than ever the physician has become the apostle of humanitarianism. By organization disease is routed; by council and group action you achieve. In this exceptional idealism to advance the profession of medicine by a public spirited united action, Wisconsin joins the vanguard of Minnesota—ever conscious that where the vanguard camps today the rearguard bivouacs tomorrow.

THE CAUSE OF GINGER PARALYSIS DEFINITELY IDENTIFIED

The cause of ginger paralysis has been determined. This paralysis, which has afflicted thousands of victims, is not caused by ginger at all, but by a compound known to chemists as tri-ortho cresyl phosphate. This chemical is the main constituent of technical tricresyl phosphate, which is widely used in trade circles, especially in the manufacture of varnishes, shellacs, and similar preparations. Being cheap and readily obtained in any quantities, it appears to have been used by irresponsible makers of so-called ginger extract to replace the ginger. There seems to be no question that the adulterated paralytic ginger extract contained tri-ortho cresyl phosphate in an approximate concentration of about two per cent.

The United States Public Health Service has been working on the public health aspects of "Jake paralysis" since the wide appearance of this condition in certain sections of the country last winter and spring. In attacking the problem, it soon became evident to investigators that they were dealing with a new form of paralysis and one in which many possibilities were involved. As the investigations proceeded, it became evident that some form of phenol was the causative agent. Soon attention was centered on technical tricresyl phosphate. Chemists of the Prohibition Bureau had found similar substances in suspected extracts. As a number of different chemicals enter into the manufacture of this commercial product, it became necessary to separate them and find out what effect each might have if used in a beverage. This has been done and it has been found that tri-ortho cresyl phosphate, either itself or in combination with other chemicals of harmless nature, when given to various kinds of animals will produce exactly the same kind of paralysis as that caused by drinking of "Jake." The Public Health Service has no record of a single case of paralysis caused by ginger preparations manufactured by reputable pharmaceutical concerns. Tri-ortho crsyl phosphate is, therefore, definitely established as the specific cause of the cases of so-called "ginger paralysis."

Studies conducted on laboratory animals show conclusively that a paralysis of the extremities can be produced uniformly in monkeys and other animals by the injection under the skin or by oral administration of the chemically pure as well as the technical tri-ortho cresyl phosphate. The failure to produce any symptoms, whatever, in monkeys with enormous doses of this poison given by mouth indicates that it is practically not absorbed from the intestinal canal in that species.

The precise reason for including this remarkable substance as one of the ingredients of a substandard fluid extract of ginger made and sold for beverage purposes will probably never be known, unless a confession is wrung from the guilty ones. It seems entirely reasonable, however, to suppose that it was included on account of its physical or other properties which make it difficult to distinguish from the normal ginger constituents. Only a chemist of considerable ability could have thought of this; and had there been anything known about the pharmacologic action of this substance and the possible dire consequences, it is probable that it would never have happened. From this the question naturally arises as to whether there are not many other organic compounds of great medicinal interest, perhaps some with great possibilities for the treatment of disease, awaiting the attention of investigators.—*Health News,* U. S. Public Health Service, December 31, 1930.

THE ECONOMIC TREND IN MEDICINE: WHAT IS IT?*

Olin West, M.D., Secretary of the American Medical Association
Chicago, Illinois

MR. Chairman, Ladies and Gentlemen:

I was somewhat dismayed as I sat over there in the corner and observed the sartorial splendor of most of the speakers who have preceded me on this program. Much as I loved George Crownhart and John Peck, I love them ten times more now that they have dared to come up here and speak to you with old suits of clothes on. For fear that you don't know, I want to tell you that both of them have not only tuxedos but have dress suits and can wear them just about as gracefully as any man can wear monkey clothes.

I am greatly pleased, Mr. Chairman, to have the privilege of participating in this meeting of the Minnesota State Medical Association, and particularly so since the American Medical Association has recently honored itself by election to its presidency of that very lovable and modest gentlemen and splendid surgeon, Dr. E. Starr Judd, one of your own members.

I note at the head of the printed program tonight what appears to be the topic of this general discussion, "The Economic Trend of Medicine," and I notice at the bottom in little letters that get smaller as one goes further down, the topic, "What Is It?" It appears that I am expected to tell you what it is. I wish I could.

Definite trends are not quickly established, but result from well considered opinion based on a reasonably broad experience extending over a considerable period. Insofar as I am able to evaluate the situation, there are not very many new trends in medicine itself. Currents are quickly developed and frequently the tendency is to drift with one or another current. Sometimes we are caught in eddies and linger there until a stronger current or a new current bears us on, or across, or even carries us back.

We are disposed, somewhat, I think, to confuse noise with trend. We are rather prone to believe that the vociferous efforts of propagandists constitute trends. Sometimes this noise and the propaganda may come from within the medical profession itself, but generally speaking most of it in latter days has come from outside.

There are agitators who love the glare of the limelight that of late years have made many proposals and have made so much fuss about them that some of us have been disposed to believe that they represented trends in medicine. There are self-seekers who would gain support for their own selfish schemes that have led some of us to think at times that these schemes represent definite trends in medicine. There are the reformers who are always dissatisfied with what is, who seek to overthrow all that is practical and to establish a sort of heaven on earth, who have fooled us at times into thinking that they represented definite trends in medicine. And I have listened to them and have wondered what sort of a situation would be created if they could realize their dreams. I cannot conceive of any hell that would be more hellish than the situation in which some of these reformers would place us, in which everybody would be like everybody else; everybody of the same mentality as everybody else; everybody with exactly the same opportunities as everybody else and with the same capacity for taking advantage of opportunities.

There are meddlers outside of the medical profession who, in my opinion, are generally actuated by the sensations that come from sore toes, that have set up one or another scheme and have fooled the public and sometimes part of the medical profession into believing that they represent definite trends in medicine.

There are misguided philanthropists who I have no doubt are actuated by the worthiest motives, that have proposed this, that, and the other scheme, and have put so much propaganda behind their schemes as to lead many to think that they constitute definite trends in medicine.

And there are the politicians of a certain kind who never lose an opportunity to take advantage of any chance that offers for multiplying votes in their favor, that have proposed and even succeeded in getting enacted into law all sorts of visionary plans supposedly for the improvement of this, that, or the other condition, and some of us have been disposed to look upon these as constituting the definite trends in medicine.

---

*Address before the Medical Economics meeting of the Minnesota State Medical Association, Duluth, Minn., July 14, 1930.

As examples of some of these activities I might mention, in passing, the enactment of legislation supposedly intended to serve the best interests of the veterans of the World War, through which will be entailed expenditures of many millions of dollars but will not result, in my humble opinion, in providing the best care for those veterans of the World War justly entitled to the best care that can be provided. These schemes contemplate extending medical and hospital service to many who served in one capacity or another who are in no sense entitled to free medical or hospital care at the expense of the government or at the expense of the general population. Under the provisions of this legislation free care is to be offered and given in cases of disease or injury that has no connection with military service. The tendency of any such scheme is to destroy the independence and the manhood and the self respect of those who accept the dole that is so offered.

There is a tendency that is very decided, promoted by those outside of the medical profession, for the most part, but aided to some extent by some of the members of the profession itself, to dissociate public health from medicine. Public health, I believe, is distinctly a field of medicine. Public health administration should be through trained medical men and should not be resigned under any circumstances, not even under the appeal of subsidies from government, to laymen without medical training and knowledge. This is a trend that did not originate in the organized medical profession, but it is one like some of the other tendencies I have mentioned, that ought to receive the most thorough and careful consideration by organized medicine and ought to be positively, militantly opposed.

There seems to have developed a very definite trend in medicine itself toward over-organization. I don't mean over-organization of county medical societies or of the state medical association, but I mean the establishment of almost innumerable independent societies and organizations of various kinds composed of the very members of the fundamental medical organization in the United States.

I am convinced that this is not for the best interests of scientific medicine and consequently is opposed to the public interest. As Mr. Crownhart said so well, there is no difference between the material interests of physicians and the material interests of the general public. I have never known anything to be done to promote the interests of the medical profession that did not at the same time, and generally to a much larger degree, promote the interests of the general public.

There is a current that I think it is well enough to mention which has been stirred by a minority element of the medical profession that tends to the commercialization of the practice of medicine. It is not a definite trend, in my opinion, because by far the greater number of physicians in the United States are actuated by the same high purposes that have always characterized the honorable profession to which they belong, and under the ideals and the traditions of the profession the making of money has never been a prime purpose. This tendency, originating upon the part of a minor element in the profession, in my judgment, is one that should be openly and persistently combated by organized medicine everywhere. When we commercialize the practice of medicine we shall destroy scientific medicine. The truly representative physicians of this country, greatly in the majority, should not permit a small minority to misrepresent their professional attitude and to prostitute a great scientific and humanitarian profession.

There is another current which stirs along the banks which should be broken *now*—also originating with a minor element in the profession, and having a tendency to break down medical ethics. This should be openly, actively, and persistently opposed by the forces of organized medicine. Remove ideals, remove tradition, remove ethics, and destroy medicine. The existence and observance of the principles of medical ethics, as written and adopted, constitutes the best safeguard of the public interest and the best safeguard of the profession itself.

But with all of these things and with others which might be mentioned, the one really big trend in medicine today is bigger and more pronounced and just as true as it has always been. It is the trend for the promotion of the art and science of medicine and for the extension of its benefits to mankind everywhere. There has never been a time when the avenues of expression of opinion in scientific medicine have been as fine and as efficient as they are today. Our medical journalism, in my humble opinion, is far superior to any journalism that has ever characterized medicine in the United States. Our medical societies, parts of the fundamental organization in this country, are becoming more and more efficient in dealing with the problems with which it is at once their right and their duty to deal. Our state societies, for the most part, have advanced in remarkable fashion within the last few years and, as has been shown here tonight in the statements of the secretary of one state society and the president of another, are taking their place in the leadership of the life of their states in a very remarkable way. As I said today on the floor of the House of Delegates, I remember distinctly having had the privilege of attending a meeting of the Minnesota State Medical Association some six or eight years ago. The atmosphere today is as different as one could well imagine, fine as the spirit was back there. The Minnesota State Medical Association has made remarkable progress in assuming the leadership that naturally devolves upon it, and in my opinion has achieved a splendid program of accomplishment within the last six or eight years. As I interpret what I have heard here today, I believe the good work has just begun, and that it is going to be carried on in a much more efficient manner than has been done heretofore.

There are undoubtedly many movements that are aimed against medicine. A regular siege has been laid. Just why I don't know; in considering the matter in my official report to the House of Delegates I tried to explain it on the ground that it may be true that we have proceeded in our honest effort to inform the public, to educate the public, as we usually say, to the point where many believe that they know enough about it to make the rules of the game and dictate procedures. A little knowledge is a dangerous thing, and if my diagnosis of the situation is correct then certainly it proves better than anything else could prove that our outstanding duty at the present time, beyond our duty to do whatever we can to make every member of organized medicine a better physician and better able to serve those who need his services, is to carry on our program of education of the public and to work unceasingly at that job until the truth about medicine shall prevail.

I don't know what is going to come of many of these currents that some of us have interpreted to constitute trends, but I am thoroughly satisfied, Mr. Chairman, that if organized medicine will bend itself with renewed determination to its fundamental job of doing everything that it can do to promote the art and science of medicine and to improve the quality of medical service rendered by every one of its members, and will then do its duty toward giving the public the benefit of useful information that none others can give and that the public can digest and assimilate, the truth about medicine will prevail and any untoward trends will be stopped.

I am grateful, indeed, Mr. Chairman, for the kindly hearing that has been given me.

HEALTH EDUCATION*

F. H. MAGNEY, M.D.
Duluth, Minnesota

HEALTH is of vital importance to everyone, and most people are intensely interested in it. It is only natural that the sick should be, in order to be relieved from pain and discomfort and so to enjoy the fruits of good health, but even the healthy wish to continue in a state of well-being, that they may further enjoy its benefits, and that life may be prolonged. This latter group has been constantly increasing and they are beginning to manifest a real interest in health and its promotion. This interest now aroused should be further stimulated, and it thus falls upon the shoulders of the medical profession to see that wise and judicious counsel be given and that this new movement shall continue to grow.

Recently, when Edison was asked what he would choose if he could have any one thing in the natural, mental and spiritual world, he replied "good health." That this desire is not only held by people of the Edison type, but by many others as well, is manifested by the continued interest taken by the millions in the syndicated health columns of the daily papers. The anagrams, limericks and many other fads have gone by the board and at present the crossword puzzle is gasping its last, but the press, feeling the pulse of the public through letters and questions stimulated by health columns, has not only continued printing such material but has added space so that often more than one doctor is carried on the individual paper's staff.

Industry is interested in the health of its employees because good health promotes efficiency, increases production and tends to prevent accidents. Through safety education and safety devices, the accidents have been cut to a minimum, but loss of time and efficiency, due to illness, is now their big problem and they are looking to the medical profession for help. They are not only supporting every move we make along this line, but are offering suggestions and creating opportunities for us to step in after they have prepared the field.

Furthermore, luncheon clubs, parent-teachers associations, churches, Y. M. C. A.s and Y. W. C. A.s, through their different fields of activity, of which "Health Week" is one well known example, are constantly clamoring for health talks.

Recognizing this demand, the medical profession owes it to the public and to themselves as well, to supply this information in order that people may profit by what scientific medicine has to offer. No company or corporation, having goods of merit, has ever suffered by having the public well acquainted with its products, but on the contrary has profited thereby, and the same applies to medical services.

While there is a great deal of interest in health education, this can be still further increased by proper propaganda. The pediatricians have proven this fact through their feeding clinics, talks before mothers' clubs and written articles distributed through private and even governmental agencies. Twenty years ago pediatrics was practically unheard of as a specialty, while today even the most humble mother insists that the growth of her child be supervised by a baby specialist.

We point with pride to the increase in the span of life during the last few years, but we often forget that practically all of this advance has been during the first year of life. When we, as a profession, have educated people to use our services in supervising their health through all the periods of life as well as during childhood, it seems impossible even to venture an estimate of the further increase in the span of life.

The St. Louis County Medical Society established a committee on public relations three years ago and the acceptance of its activities, by the public, has been most gratifying. While its policy has been passive, in supplying a demand rather than trying to force a definite program on the public, neither it nor its individual members have missed an opportunity to make known that they are at all times willing and ready to supply medical information whether it be in the form of a talk or by a written article. A speakers' bureau was first established and a card index system was set up, carrying names, addresses, telephone numbers of speakers, types of meetings they preferred to talk to and the subjects they were interested in. A record of the talks given has been kept on each man's card for the sake of future reference. The committee has in no way discouraged any speaker talking on his own initiative apart from the agency of the speakers' bureau, but on the other hand has rather encouraged it as long as the talks were delivered unselfishly and in the interest of health and the profession. It has been interesting to note that there has never been any expression of suspicion that any member of the medical society was seeking too much publicity through public expressions since the establishment of this bureau, while before its organization such statements were frequently suggested.

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 14, 1930.

A class in public speaking, limited to doctors, was organized and given by the University Extension Division. This covered a period of one semester and the nature of the instruction was especially planned to prepare those taking the course to give short talks. The didactic phase was made to cover as little of the time as possible and more time was devoted to the actual experience of giving talks before the class. Approximately twenty per cent of the profession in the city registered for the course.

Short résumés of scientific papers presented before the society have been prepared for the daily papers, stressing those parts which would be of special interest to the public. While this brought the names of the authors of these papers into print, we felt that any publicity they might get in this manner acted as a reward for their efforts in preparing and presenting these papers and the same privilege has been open to any member willing to work.

One of the daily papers publishes a babies' section annually through the help of the society. The motive prompting this issue is the selling of advertising space to merchants selling infant supplies, but in order to do so it must have articles on babies' health, which are supplied by the pediatricians. This affords an opportunity to stress the value of inoculation and vaccination and many other things, which makes the issue of mutual benefit to all concerned.

Parent-teacher associations of the different public and parochial schools of the city have been the most consistent bidders for health talks, the calls coming constantly throughout the entire school year. The subjects for these talks have been selected with the idea of giving the mothers health suggestions, which are most appropriate for the ages taught in each particular school. When the parents represent children of the lower grades, toxin-antitoxin, vaccinations and inoculations are discussed in keeping with the program outlined for the year by the Public Relations Committee of the Minnesota State Medical Association. If the audience represents children of high school or junior high school age, goiter and tuberculosis are the subjects most often chosen.

Another consistent avenue for our propaganda, which is open throughout the entire year, is the service or luncheon clubs. The approach is usually made through members who belong to the profession. The program committees of these clubs are constantly on the lookout for speakers and are very easy to approach. The speaker usually talks on some phase of medicine that he is interested in, although at times such subjects as the cost of medical care and periodical health examinations have been used.

At times the demand has become so great that the duties of the committee are rather burdensome. This is especially true when some organization puts on a "Health Week" program and stresses some certain phase of health. Fortunately, in these cases the talks are all on the same subject and prepared material is usually available for the speakers. On one such occasion, we were called upon to supply sixty speakers in one week. The formality of asking our members to supply this request was done away with and they were simply drafted and given assignments. As a tribute to the loyalty of the profession in Duluth, it is only fair to state that the response was one hundred per cent.

The most successful event of our activities was a program sponsored by the Industrial Committee of the Duluth Chamber of Commerce when they gave us one of the five evening meetings sponsored by the committee for the year. The audience consisted of superintendents and foremen from ninety different companies of Duluth and surrounding territory. These men, being superintendents and foremen, were naturally the more alert and intelligent workmen, whose duty was to bring the message back home to the men working under them, which naturally called for very close attention on their part. Those who came from out of the city were given a day's wage, transportation and expenses by their employers. They were assembled in seven different sections, classed according to their special work, and each section was given a forty-five minute talk by members of our local society. The subjects of these talks were chosen with the idea of stressing health hazards most common to the men in the different trades, as, for instance, neglect of common colds being the subject of the talk for the dock and elevator section. Following these sectional meetings, the whole audience was assembled in a hall and was given a forty-five minute talk on "Personal Health and Efficiency" by Dr. W. A. O'Brien of the University of Minnesota. The registration showed an attendance of 960 at this meeting, and these men received the message directly, while thousands received it indirectly through their superiors at their places of work, not to mention the families of these men. We have already been requested to supply speakers for similar meetings next winter.

While we cannot lay claim to anything original in our program, we have definitely demonstrated that there is a demand for information on health and that the public is anxious to get it direct from the medical profession. Doctors have been criticized, and justly so, for being too "close-mouthed." This has left an opening for irregulars and cults, who have not hesitated in handing out their particular brand of wise counsel. In not one single instance has it come to our attention that a cultist or irregular has had an opportunity to speak before an audience in Duluth during the last three years, unless he has rented a hall and advertised for listeners.

In view of our experience it seems to us that it would be profitable for every county society, whether large or small, to have an active committee on public relations, who will stand ready to supply the public demand and supervise the types and nature of information given out. Their experience may be entirely different from ours, depending upon the community and local conditions. Avenues may develop that do not exist here or that we have not recognized, but we are sure that just as soon as the public finds out that the local medical profession has raised the self imposed censorship on their own free advertising, they will invite them to broadcast the merits of their goods and thank them for doing so.

EFFECT OF METHANOL ANTI-FREEZE ON HEALTH

Surgeon General H. S. Cumming of the United States Public Health Service, when asked regarding the statement issued December 6 by the Bureau of Mines on the effect of methanol anti-freeze on health, stated that the Public Health Service had kept in touch with the observations being made by the Bureau of Mines on the subject, and that he felt there was need for the immediate release of information which would protect the general public. It appeared from the study so far that there was much more danger from exhaust gas (carbon-monoxide) than could possibly come from methanol when used strictly as an anti-freeze liquid in automobiles.

The greatest danger is that some one might drink methanol, especially in view of its being used in place of ordinary denatured alcohol as an anti-freeze, and in view of its other name, methyl alcohol. Methanol when taken internally is more certainly poisonous and more highly fatal than any denatured alcohol. According to press accounts, such poisoning has recently occurred in Pennsylvania.

Another danger is in the use of methanol in shellacs which might be applied over considerable surfaces without adequate ventilation. The presence of the coloring matter, as recommended by the Bureau of Mines, and the addition of 23 per cent water as at present dispensed, guard anti-freeze methanol against such dangerous use.

A complete study is advisable as to how far methanol can be used by the general public as an anti-freeze only, and that the precautions advised by the Bureau of Mines be strictly observed.—*Health News*, U. S. Public Health Service.

WOUNDS OF THE THORAX*

Ben F. Davis, M.D.
Duluth, Minnesota

I SHALL confine myself principally to a discussion of penetrating wounds and under this head shall discuss wounds of the heart, pericardium, pleura, and lungs.

HEART AND PERICARDIUM

The heart has been injured by a great variety of objects; while the majority of such objects have entered the heart through the chest wall, wounds of the heart have been produced by objects penetrating from the esophagus, from the bronchi and from the blood stream. The majority of wounds are produced by projectiles, most commonly bullets, although a high percentage are produced by sharp objects; knives, needles and pieces of glass head the list.

It is estimated that patients with wounds of the heart have one chance in ten of spontaneous recovery. Wounds of the right ventricle are more serious than those of the left and wounds of the auricles are more serious than those of the right ventricle. Wounds of the thin-walled auricles do not tend to close. From the left ventricle the blood usually comes in spurts; from the right ventricle and the auricles, in a steady stream. Wounds of the bundle of His are often immediately fatal and wounds of the coronary arteries, proximal to the bifurcation, are fatal and ligation above that point is fatal. Wounds of the heart heal by the formation of scar tissue, not by regeneration of muscle, so that aneurysms in such scars, and spontaneous rupture following strain, frequently occur.

It is estimated that in civil practice at least 60 per cent of all wounds of the heart, not immediately fatal, should be amenable to surgical treatment; that approximately 50 per cent of the patients operated on should recover; that the mortality is about 5 per cent higher for stab wounds than for gunshot wounds and that about 2 per cent of the deaths are due to pulmonary embolism.

Common causes of death in the operated cases are: sudden stoppage of the heart during the operation; infection, which is fairly common, only about 25 per cent of the patients that survive operation being free from infection; and rupture of the scar.

Patients with a wound of the heart usually present an external wound in the precordial area from which blood may or may not be escaping; the pulse is rapid, the blood-pressure is low and tends to fall lower, there is marked precordial distress and dyspnea and the patient may be extremely restless, sometimes tossing about in the wildest manner. In such instances, the pericardium will be full of blood and, if relief is not rapidly given, death will result from pressure on the auricles. It has been shown that when the pressure in the pericardium equals the venous pressure, the heart stops. The average amount of blood in the pericardium in such cases is about 250 grams, although larger amounts up to 500 grams have been described. In other cases the precordial distress is not a prominent symptom, but signs of hemothorax or hemopneumothorax are found. In such instances the pleura has also been opened and the blood escapes from the pericardium into the pleural cavity. *X*-ray examination may be of value if it is quickly available, by showing the rounding out of the pericardial shadow and, in cases of associated wounds of the pleura, showing the changes incident thereto. Most of these cases, however, are urgent and no time should be lost if the radiologist is not at hand. Practically all wounds of the heart should be operated on as soon as the diagnosis is made.

There has been some question with regard to the removal of a foreign body which may be projecting from the wound in the thorax. Needles thus projecting should be removed at once as they are very apt to be drawn into the tissues, to change their location and to be very difficult to find. It is problematic whether to allow other objects to remain in situ until all preparations for operation have been made. Possibly the chances of wound infection would be decreased if such objects were removed at once and further damage to tissues by the foreign body would be prevented. On the other hand, it is conceivable that hemorrhage might be greatly increased and, because this is the great danger early in these cases, we hesitate to do anything that may augment this risk.

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 14, 1930.

TECHNIC

Most operations for wounds of the heart may be done under local anesthesia. At times, however, the restlessness of the patient is uncontrollable and in such cases Lockwood[2] recommends "mass ether." In less than one minute the patient is completely relaxed and the operation may be proceeded with.

A great variety of incisions have been suggested. Those of Ollier, Kocher and Mintz, involving, respectively, an incision to, with removal of, the fifth, sixth or seventh left costal cartilage, are frequently chosen. Better approach is afforded by one of the flap operations, with a hinge to the right or left, as preferred by the operator. All of these operations involve the turning up of a flap of the entire thickness of the chest wall, usually including the fourth and fifth costal cartilages, with or without a portion of the corresponding ribs, and, occasionally, a section of the sternum. In other instances, particularly those in which hemothorax exists and it is thought advisable to explore the pleural cavity, the modified Spangaro incision gives excellent exposure. By this incision the fourth and fifth costal cartilages are cut close to the sternum, the thoracic wall is incised in the fifth interspace and the fourth and fifth ribs are widely separated by means of a retractor. This incision gives a good view of the left and right ventricles, the pericardium, and the left pleural cavity. In cases in which a rapid exposure of the heart is not essential, the so-called median-thoraco-abdominal pericardiotomy operation of Duval and Barnsby has been recommended. Briefly, this operation consists in transverse section of the sternum below the angle of Ludwig, longitudinal slitting of the sternum from this point downward carrying the incision two or three inches below the xiphoid into the linea alba. With the pericardium opened and the incision carried inferior to the heart for a short distance through the pericardium and diaphragm, practically the entire heart may be exposed.

When the pericardium is reached, through any of these incisions, it may be split widely and the heart becomes available for examination. In the great majority of instances, the wound of the heart will be found on the anterior surface and immediately two problems arise: (1) the immediate control of hemorrhage; and (2) the control of the excursions of the heart to permit the introduction of sutures. Hemorrhage may best be controlled by placing the finger over the wound and into it if necessary. The matter of steadying the heart for the introduction of the sutures may be quite difficult. It has been recommended that the hand be passed posterior to the heart and that the organ be partially dislocated from the pericardium. This procedure is strongly objected to by recent operators, who feel it is likely to cause permanent arrest of the heart. Lockwood[2] strongly advises the use of the Beck method, according to which a stay-suture is passed through the apex and is held by the thumb and middle fingers of the left hand while the index finger plugs the opening in the ventricle. Interrupted sutures of No. 0 chromic catgut or black silk, carried on fine, non-cutting needles, are then placed in sufficient numbers to control the bleeding and close the wound. The sutures should not enter the cavity of the heart.

It was pointed out long ago that the pericardium and heart do not stand handling as do the pleura and peritoneum. Therefore, sponging with gauze is contraindicated and pads of absorbent cotton, wrung out in warm water, are probably better. An aspirator attached to a suction pump may be used to remove material from the pericardium. Irrigation by any sort of solution produces a serous effusion, with subsequent adhesions, and should be avoided. One curious fact appears, namely, that blood retained within the pericardium seems to be absorbed without the production of adhesions. Drainage should not be employed provided hemorrhage has been completely controlled and excepting in late cases with retained, infected missiles and infection already established. Lockwood[2] advises carrying a double silk suture from the dependent portion of the incision in the pericardium to the surface to act as a guide for the passing of a curved forceps into the pericardium. If such a procedure is not required by the eighth or ninth day, one end of the suture is cut short and the remnant pulled through. If drainage is required, a Penrose drain placed dependently is best. Suture of the edges of the pericardium to the surface for open drainage is advisable in well established infection.

If the pleura has been opened during the operation, it should be hermetically sealed.

Lockwood[2] tabulates the dangers and complications of cardiorraphy for wounds of the heart as follows:

Sudden arrest of the heart.

Jagged, irregular wounds that cannot be approximated.

Tearing of the wound while being sutured.

Hemorrhage that in a certain percentage of cases can hardly be checked.

Infection.

As late post-operative complications he adds:

Adhesions to the pericardium.

Dilatation of the heart.

Dilatation of the heart and adhesions to the pericardium.

Extrasystoles.

An irritable type of heart with recurring tachycardia.

Fortunately, late post-operative complications are uncommon.

LUNGS AND PLEURA

As contrasted to patients with wounds of the heart, most patients with wounds of the lungs and pleura survive long enough to reach the hospital.

The common causes of wounds are: (1) fractured ribs with tearing of the pleura, intercostal vessels or lung by the sharp ends of the rib; (2) penetration by sharp objects; and (3) missiles. The parietal pleura alone may be wounded or the wound may include the intercostal vessels and the lung. Not uncommonly, wounds in the lower part of the thorax traverse the diaphragm and produce intra-abdominal injury.

The signs and symptoms of a wound of the chest may be: (1) slight or no external bleeding, with moderate shock and signs of pneumothorax or hemopneumothorax; (2) external wound with or without external bleeding but with rapidly developing dyspnea, shock, rising dullness in the chest and displacement of the mediastinum; (3) sometimes, with or without cough and spitting of blood, one may see the so-called sucking chest, in which air and blood pass in and out of the wound with the respiratory efforts; and (4), occasionally one may find a patient with increased distension of the affected site with alarming dyspnea, shock and displacement of the mediastinum to the opposite side without dullness, the *x*-ray showing a collapsed lung. With these symptoms there may be signs of peritonitis.

The treatment of wounds of the chest will be guided by the symptoms. It is to be remembered that a wound of the chest causes death by hemorrhage, by asphyxia and by infection, to which may be added syncope, probably due to mediastinal distortion, especially in wounds of the left side. These general points govern the indications for treatment. The difficulties and dangers associated with exploration of the chest and the difficulties of locating the site of internal injury make it advisable that, in general, the treatment should be expectant.

Excluding certain conditions which will be discussed shortly, in dealing with any wound of the chest, irrespective of the agent producing it, the general practice ought to be, to make no exploration; to disinfect the parietal wound and close it immediately; to keep the patient absolutely quiet and under strict observation; and to wait. To these measures we may add, external heat, hypodermoclysis, blood transfusion and morphine as indicated. Absolute quiet is the first requisite for the expectant treatment of thoracic wounds and any departure from this rule is fraught with danger.

Active interference is demanded by: (1) marked hemorrhage, with or without spitting of blood; (2) injury to the diaphragm or signs of peritonitis; (3) increasing distention of the chest with collapsed lung; (4) infection; (5) spreading emphysema.

Brisk external hemorrhage is likely to arise from a wounded intercostal artery. This is best controlled by enlargement of the wound, exposure and subperiosteal removal of the section of rib immediately above the wound to reveal the wounded vessel and to permit ligation of it by two ligatures, one on each side of the site of bleeding. Profuse hemorrhage may come from a wound of the lung and may or may not be associated with spitting of blood. Such hemorrhage demands that the pleura be widely opened and a direct attack be made on the wound in the lung. For this purpose one may lay back a large osteoplastic flap or, better perhaps, make a long intercostal incision and enlarge the opening with a rib spreader, bring the lung to the surface and suture all bleeding points, of which there are frequently more than one.

If, on exploring a wound of the thorax, it is found that the diaphragm has been penetrated, the opening in the latter should be enlarged sufficiently to permit of finger exploration of the sub-diaphragmatic area, and any lesions thus found may be repaired by the same route. Symptoms of peritonitis, namely, abdominal pain and rigidity, appearing quickly after the receipt of a thoracic wound are probably more safely met by laparotomy.

Cases of pressure pneumothorax are more frequently spontaneous in origin than traumatic. Nevertheless traumatic cases are encountered. This demands release of the air pressure within the pleura. This may be obtained by slipping a catheter through a cannula between the ribs and attaching it to a siphon bottle or in one of several other ways which are well standardized.

Infection demands adequate drainage. My preference is for rib resection, evacuation of infected blood clots and exudate, and the introduction of one or more moderate-sized rubber tubes.

Spreading emphysema means that air is being pumped into the tissues at the site of a wound. This condition usually is due to the lung being caught and punctured by the broken rib and held in the wound so that air escaping from the lung is forced along the opened tissue planes. The condition may develop in cases in which air enters the chest through the wound on inspiration but escapes with difficulty on expiration and is deflected into and along tissue planes. Emphysema may spread between pleura and ribs to the mediastinum and there cause serious trouble, or may travel over the body subcutaneously to involve the organs of the neck and endanger life by asphyxia. The remedy is to be found in operation on the wound in the chest.

As in surgery of the heart and pericardium, so with the lung and pleura—a great deal can be accomplished under local infiltration and nerve-block anesthesia. Ethylene anesthesia is quite satisfactory for chest work for the surgeon who does not wish to use local anesthesia. According to Koster and Kasman[1] of Brooklyn spinal anesthesia is entirely practicable for thoracic work and may soon prove to be the anesthetic of choice.

ALBUTESTA, A PROPRIETARY REAGENT

The A. M. A. Chemical Laboratory reports that Albutesta is a coined name for a chemical reagent to detect albumin in urine. The makers of this product, Menley and James of London, England, and also of New York, have been noted in the past for unscientific proprietaries. One of these is "Iodex," for which the firm has claimed that it contained 5 per cent of free iodin, although the A. M. A. Chemical Laboratory showed, first, that the product did not contain iodin in the free form but in the combined form, and, secondly, that there was less than five per cent of total iodin present. The Laboratory later analyzed the companion proprietary "Liquid Iodex," which was claimed to be a non-irritant preparation of iodin and to contain "free iodine," and found it to contain only about 0.16 per cent free iodin and about three-fifths of the total iodin claimed. The Laboratory found "Albutesta" to be nothing more than a solution of sulphosalicylic acid, a substance well known as a clinical reagent for albumin. The Laboratory points out that while "Albutesta" sells for one dollar, the cost of the ingredients of one ounce of such a solution is about five cents. Since the identity of "Albutesta" is not declared by Manley and James, the Laboratory reminds us that it is almost axiomatic that an analyst must know the composition or definite attributes of reagents he is using if he expects to be at all scientific. (Jour. A. M. A., November 1, 1930, p. 1347.)

HEAD INJURIES*

Winchell McK. Craig, M.D.
Rochester, Minnesota

Head injuries are so variable in severity and effect that only a general, and not a definite, plan of procedure can be outlined for the purpose of diagnosis and treatment. The immediate results of such injuries, although of utmost importance, should not eclipse the consideration of delayed or latent symptoms, which may subsequently become apparent. Certain physiologic and pathologic observations, contributed by neurosurgeons, have been of definite assistance in the improved treatment of patients with head injuries.

At one time, head injuries usually were considered to be severe only if a demonstrable fracture of the skull was present. If a fracture was found, treatment varied with its type and generally consisted of rest, supportive measures, and decompression. This conception of severity of injury was adopted inasmuch as it was thought that the skull, with its rigid structure, acted as a protection to the intracranial contents, and that only a break in the continuity of its walls permitted injury to the underlying brain. But head injuries, with no demonstrable fracture of the skull, produced unconsciousness, aphasia, hemiplegia, altered blood pressure and pulse, and even death. Postmortem examination revealed definite injury to the brain, associated with hemorrhage, both gross and microscopic, not only in the region of the injury, but also in remote regions.

In the search for an explanation of these observations, it was found that the skull was flexible and elastic to a considerable extent and that it yielded, locally or generally, corresponding to the amount of trauma and the manner in which it was received. Such distortion of the intracranial cavity adequately explained the injury to its content, and in the absence of demonstrable fracture it was assumed that the flexibility of the skull prevented a definite break. Consequently, the significance of fracture of the skull in determining the severity of head injuries became modified, and although the presence of a fracture may be considered an index to the violence to which the brain has been subjected, the absence of fracture is not evidence that the skull has not been seriously distorted or the brain injured. Any consideration of head injuries should assume that the injury to the brain and its non-bony coverings is of primary significance, although determination of the presence or absence of a fracture is of interest from a medicolegal standpoint, and extensive linear fractures, particularly of the base of the skull, indicate the seriousness of the situation.

For convenience, acute head injuries are usually clinically divided into three general groups. The first group contains those cases which are relatively mild, in which alarming symptoms do not develop, and in which recovery takes place under expectant treatment. The second group contains the largest and most interesting group of cases. It is considered the most important clinically because it contains the borderline cases, in which the reaction is latent and symptoms develop while the patients are under observation. The third group comprises those cases in which the injury is so severe that the situation appears hopeless from the beginning and death rapidly occurs, in spite of treatment.

In view of the fact that often it is only under careful observation that distinction can be made of cases of these three groups, it is imperative that treatment and observation be closely correlated, and that in all cases, mild or severe, expectant treatment be given. This seems more important when it is realized that the majority of the patients with head injuries of the more serious type suffer from shock which at times masks the underlying injury to the brain. Consequently, in order to determine the extent of the injury, the patient should be put to bed under close surveillance as soon as possible after the accident, and treated for shock if necessary.

The repair of minor cuts and lacerations can be done during the treatment for shock, but any attempt to repair compound fractures and lacerations should be postponed until the general condition of the patient has improved. The pulse, blood pressure, and respiration should be taken and recorded at least every fifteen minutes. After the patient has sufficiently recovered from shock, then any radical surgical procedures can be performed, and more detailed examinations, including roentgenologic, can be made.

---

*From the Section on Neurologic Surgery, The Mayo Clinic, Rochester, Minn. Read before the Minnesota State Medical Association, Duluth, July 14 to 16, 1930.

When lacerations of the scalp and compound fractures of the skull have occurred, the area involved should be carefully shaved, the ragged edges of the scalp should be trimmed, and the wound should be swabbed out with tincture of iodine, or a similar antiseptic preparation. After removal of any foreign material and contaminated fragments of bone from the wound, iodine should be applied to the dura and cortex, and capillary bleeding should be controlled. Following this, the skin should be loosely closed with sutures of silk or silkworm gut.

Increased intracranial pressure, after trauma, usually begins a few hours after the period of shock is over and forms a serious complication in head injuries. For this reason, treatment should be directed toward its relief, and in view of the fact that increased intracranial pressure may be caused by either cerebral edema, or intracranial hemorrhage, conservative methods of treatment are advisable until there are definite indications for operation. Edema is a physiologic reaction on the part of any traumatized tissue of the body, and since the skull acts as a capsule of constant volume, preventing expansion of the brain when traumatized, two conservative methods of treatment can be used for the relief of subsequent intracranial tension. The first consists in the drainage of the cerebrospinal fluid from the subarachnoid space, by spinal puncture, which relieves the pressure within the cerebral ventricles. Formerly, this was thought to be a rather dangerous procedure because it tended to increase intracranial hemorrhage, if present, but following the observations of Bagley, who demonstrated the irritative action of blood on the meninges, any danger associated with drainage has been seen to be less than its beneficial effects. Spinal drainage should be repeated when it is followed by improvement and when, in the course of a single puncture, the fluid becomes clear after first being hemorrhagic.

The second conservative measure consists of intravenous administration of hypertonic fluids, which aids in lowering the intracranial pressure. Fay not only advised intravenous injection of 50 c.c. of solution of glucose, 50 per cent, but also suggested that the intake of fluid be restricted to 26 ounces (800 c.c.) in twenty-four hours. If rapid pulse indicates that more fluids are necessary, glucose, 20 per cent, in physiologic solution of sodium chloride, can be given intravenously in amounts up to 500 c.c., and oral intake of fluid can be increased. Administration of magnesium sulphate further aids toward cerebral dehydration and reduction of intracranial pressure, and, when the patient is conscious, should be given by mouth in doses of 1½ ounces (45 gm.). When the patient is unconscious, administration should be by rectum in doses of 3 ounces (90 gm.) in 4 fluid ounces (120 c.c.) of water.

If the patient continues to exhibit symptoms of increased intracranial pressure, such as stupor, slow pulse, and elevated blood pressure, then decompression may be considered. If localizing signs cannot be elicited by careful neurologic examination, right subtemporal decompression may be done. Linear fractures, without accompanying paralysis, rarely require exploration. However, extensive depressions in the skull should be elevated, and the fragments should be retained and held in place by the scalp, in the absence of external lacerations. Plastic operations to relieve depressions of the skull in the presence of infected wounds should be postponed until all evidence of infection has disappeared. Antitetanic serum should be administered when lacerations have occurred.

Middle meningeal hemorrhage may not become evident until apparent recovery from acute head injuries has taken place, and it may follow even mild trauma. Consequently, careful observation and repeated neurologic examinations are imperative in all suspected cases. Slowly developing intracranial pressure, accompanied by hemiplegia, jacksonian attacks, changes in reflexes, or similar localizing symptoms, usually indicate the presence of hemorrhage. Besides other localizing manifestations, Jefferson has called attention to bilateral rigidity as a diagnostic sign in the presence of middle meningeal hemorrhage. Following the development of localized compression and the diagnosis of intracranial hemorrhage, operation should be performed to arrest the bleeding and to remove the associated blood clot.

In the treatment of acute head injuries, it is necessary to consider the fact that in some cases of relatively mild injuries unpleasant sequelæ develop at a later period. These consist of intermittent headaches, irritability, loss of concentration, of memory, of judgment, of ambition, and even convulsive disorders. Repeated neurologic examinations often fail to reveal any evidence of altered function, and a diagnosis may be made of posttraumatic neurosis, hysteria, neurasthenia, and even of malingering.

Following the introduction of air into the subarachnoid space and ventricles by Dandy, it has been possible to study such cases by means of ventriculography and encephalography. Roentgenograms of the head give evidence that some of these patients have a definite pathologic lesion, consisting of atrophy of the brain, involving chiefly the frontal and parietal lobes. This has come to be regarded as atrophy due to pressure which, in turn, is caused by a disturbance in the mechanism by which cerebrospinal fluid is eliminated. Normally, physiologic balance exists between the secreting mechanism of the cerebrospinal fluid, or the choroid plexus, and the eliminating mechanism, or the subarachnoid villi and pacchionian bodies. The meningeal irritation resulting from blood in the cerebrospinal fluid following trauma has been referred to. Bagley carried out experiments and made clinical observations which proved that the irritative effects have a tendency to disturb this balance by interfering with elimination of cerebrospinal fluid. As a result, it is believed that, following head injuries, there occurs an accumulation of fluid over the cortex, with subsequent atrophy of the brain. Owing to this fact, it is possible to demonstrate, by means of encephalography, any atrophy of the brain associated with the so-called posttraumatic syndrome. Penfield has advocated the use of insufflation of air as a therapeutic measure in cases of chronic head injury, and some of the posttraumatic headaches have been relieved by this method. At the time of the insufflation, Penfield has roentgenograms made, and on the basis of what they reveal he gives tentative prognosis and gains ideas which can be employed in future treatment.

There is a relatively small group of patients with head injuries in whom latent symptoms develop after an interval of weeks, and sometimes of months, and the injury may be so insignificant that it is omitted from the history. The usual clinical picture consists of a slowly developing rise in intracranial pressure, with few, if any, localizing signs. These patients may go on to coma and death. The underlying cause is the formation of a chronic subdural hematoma or organizing hemorrhage beneath the dura. A correct diagnosis is difficult and ventriculography or exploratory craniotomy is sometimes necessary to reveal the nature of the lesion. The removal of the hematoma results in prompt recovery, and for this reason in every case of head injury in which late symptoms of increased intracranial pressure develop, hematoma should be considered.

In the treatment of old head injuries, it is often necessary to decide whether plastic operation should be carried out. This is especially true when depressed fractures have occurred or when defects in the skull exist as a result of a previous operation. The use of encephalography may demonstrate associated atrophy of the brain, in which case the symptoms will not be relieved by repair of the defect or by elevation of the depressed bone. Even in the absence of atrophy of the brain, a small defect within the hairline, which has not produced symptoms, should probably be left alone. Larger defects in the skull usually are repaired by means of either the Koenig-Müller osteogenic flap, consisting of the periosteum and the outer table of an adjacent area of bone or implanatation of a celloidin plate. Either of these procedures is more satisfactory than the insertion of a silver plate. Deformity of the frontal bone is usually repaired by transplantation of a portion of a rib. In chronic cases, when operation offers little, if any, relief, patients should be advised regarding a change in environment and occupation; they should be encouraged to occupy their time in light work and gradually to increase their activities. Sedatives can be given when necessary and the intake of fluid restricted. With proper adjustment and encouragement, such patients often improve and ultimately recover.

SUMMARY

Head injuries respond to treatment in proportion to the injury to the brain.

Fracture of the skull, although indicative of the severity of the injury in some cases, does not always occur even in the more severe types of head injury, due to the flexibility of the bones of the skull.

Radical surgical treatment should be delayed until the patient has recovered from shock, although minor lacerations can be cared for while shock is being treated.

Spinal drainage should be effected to relieve increased intracranial pressure and to remove hemorrhagic spinal fluid which may irritate the meninges and contribute to the posttraumatic sequelæ.

Dehydration by means of intravenous hypertonic solution, oral and rectal administration of magnesium sulphate, and restriction of intake of fluid, controls the increase of intracranial pressure, may obviate the necessity for surgical intervention, and tends to prevent the development of latent symptoms.

Encephalography is of value not only in diagnosing the presence of organic changes in the brain, but the insufflation of air that the procedure entails tends to relieve posttraumatic headache.

Surgical repair of old injuries to the skull should be done only in the absence of any organic change in the brain, and the operations of choice are the Koenig-Müller graft, insertion of a celloidin plate, or transplantation of a portion of a rib.

NEW NAMES FOR OLD UNACCEPTABLE PROPRIETARY PRODUCTS

The Southwest Medical Supply Company sends out advertising for "Onolin," "Aritine," "Amazine" and "Lesol." Those who read a recent discussion, "The Horovitz Proteins and Lipoids Again," will recognize in the products named the ill concealed names of Gonolin, Arthritine, Asthmazine and Luesol. Here is a group of the various names under which the Horovitz proteins and lipoids are marketed by various firms. The advertising circulars that are sent for one group are the same (except for the name of the product) as those sent for the other group, the genealogy of which has been traced from the original Horovitz mixtures, through the Merrell Proteogens, to the present products of the Lipoidal Laboratories, Inc. The advertising for each is a farrago of pseudoscience. (Jour. A. M. A., December 20, 1930, p. 1933.)

SOMNOFORM

Yandell Henderson writes that he has recently received from the Stratford-Cookson Co. an advertisement of "Somnoform," stated to have the formula: chloride of ethyl, 83 per cent; chloride of methyl, 16 per cent; bromide of ethyl, 1 per cent. Henderson believes that if the claim is true that "the record of Somnoform for safety is without equal," the record must be regarded as a pure piece of good fortune, for two at least of the ingredients have a toxicity which renders them unfit for use as anesthetics. In 1919 the Council on Pharmacy and Chemistry declared Somnoform inadmissible to New and Non-official Remedies because in the absence of acceptable evidence showing its exceptional safety and value, the claims made for it were held to be unwarranted and because the name of the mixture is not descriptive of its composition. (Jour. A. M. A., November 8, 1930, p. 1445.)

THE DAVIS TREATMENT OF COMPRESSION FRACTURES OF THE SPINE WITH A SUGGESTED METHOD IN DISLOCATIONS*

EDWARD T. EVANS, M.D.
Minneapolis

THE daily increase in the dangers to which our civilian population is exposed has resulted in a corresponding increase in traumatic surgery. The public is demanding more and more the ultimum in the treatment of these injuries, and the failure of members of the profession to acquaint themselves with and to grasp the improvements in fracture treatment will react to their detriment.

Up to the time of the *x*-ray, a spinal injury, if recognized as neurological, was treated in many instances as an almost fatal condition. Without neurological signs, it often went untreated with good, bad or indifferent results and the situation was clouded by the pessimistic attitude of the profession and layman.

Within the past ten years conditions have improved markedly. Rational treatment, often life saving in effect, has marked the severe injuries. C. C. Coleman of Richmond, Virginia, contributed a real advance in the early diagnosis of cord block when he advocated Ayres technic of double spinal puncture as a routine in the neurological cases of fractures and Neffziger summarized the indications for radical surgical treatment before the Pacific Northwest Medical Association in January, 1927.

But the cases with neurological signs are in the minority; 60 to 80 per cent of fractured spines are of the compression type.

Osgood states that 70 to 80 per cent of these compression fractures lie between the eleventh dorsal and second lumbar vertebra, with the region from the fifth cervical to the fourth dorsal following in frequency. The occurrence of double lesions must not be overlooked.

In 1923, Wallace, recognizing the inadequacy of flat bed or ambulatory brace treatment, made a distinct contribution to the prevention of increasing deformity, so common after these cases, when he advocated traction upon the hyperextended frame.

In 1924, I treated three cases of severe compression fracture with lamina injury and paralysis by constant hyperextension of the patient over a taut sheet. My notes remark that on the fifth day no kyphos was palpable in one of the cases and the *x*-ray reported a diminished impaction, but I failed to appreciate what had occurred and did not fix the patient in hyperextension and the end-result was mechanically poor and the kyphos recurred, though the paralysis cleared up completely. No diminution in kyphos was apparent in the other two, though my hyperextension was quite extreme (Fig. 1).

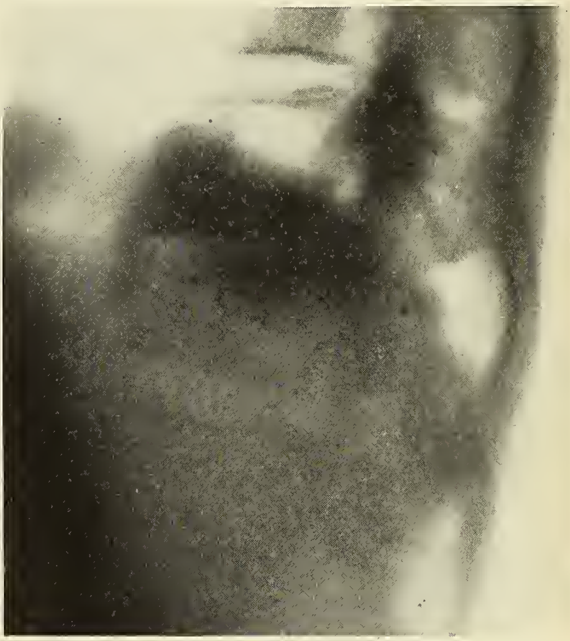

Fig. 1. Typical result in unreduced cases.

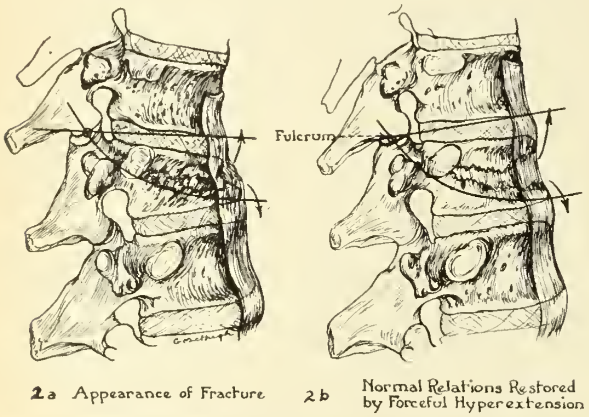
In April, 1928, J. E. M. Thomson reported a case in which he applied plaster in prone hyperextension on the hammock. His *x*-ray shows improvement. A. Thomas reports the end-results in 100 cases treated by hyperextension, according to the Wallace method, with the usual high percentage of disability, and no recorded reductions.

---

*Delivered in part before the Great Northern Railway Surgeons at Seattle, Washington, July 2, 1929, and in full before the Minnesota State Medical Association at Duluth, Minnesota, July 14, 1930.

Eikenbarry of Seattle stated that not more than 5 per cent of his series returned to hard labor without considerable permanent disability. H. I. Johnson reports that most of his series ran from 60 to 70 per cent permanent disability. Cases summarized by Dr. Kuth of Duluth, showed a lower disability but enough cases of high disability in simple compression to make one pause and ask if our treatment has been sufficient.



2a Appearance of Fracture

2b Normal Relations Restored by Forceful Hyperextension

Fig 2.

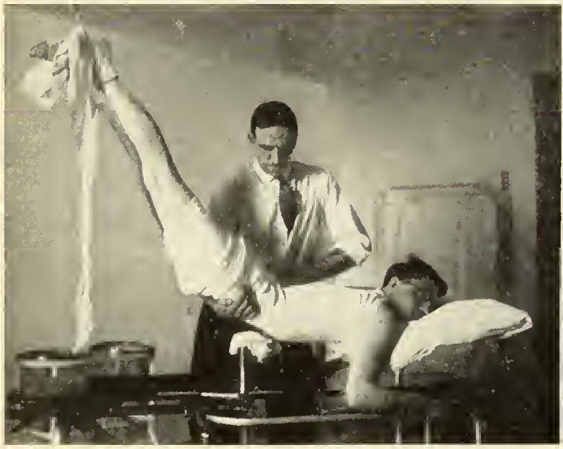


Fig. 3.

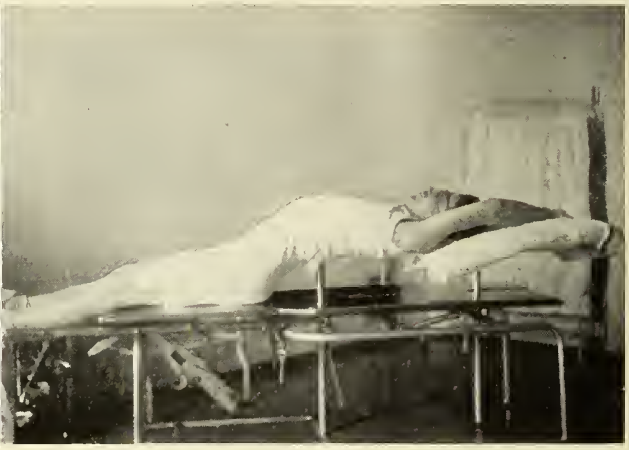

Fig. 4.

The compensation angle must be recognized as an economic factor in these cases. It is a well known fact that the private patient recovers quite rapidly from the simple compression fracture, whereas the industrial case is less prone to do so. Two factors account for this. First, the uniformly heavier type of labor necessitating full function of the spine. Second, the dependence, conscious or subconscious, on compensation until all subjective symptoms disappear, often prolonging disability until long after objective findings are gone. We must confess that the functional and static condition of the spine is disturbed with resultant osteoarthritis, a common sequela; and too often the industrial commissions base their rating on the *x*-ray findings.

Arthur Davis of Erie, Pennsylvania, in his American Orthopedic Association thesis, contributed the greatest single advance in the treatment of this type of case in the use of hyperextension with forcible manipulation. He applies rational and sufficient mechanical leverage to reduce the compression by reversing the forces producing the fracture. Rogers of Boston has accomplished the same by means of an adjustable hyperextension frame, but this, I believe, calls for special apparatus, requires more time and is more painful, though probably indicated in certain severe comminuted fractures.

The vertebral body is spongy bone throughout, except the superior and inferior plates, which are of compact bone and which form from separate epiphyses at about the twelfth to fourteenth years and fuse to the body at the twentieth to twenty-fourth years. The bodies are separated from each other by intervertebral discs sufficiently elastic in structure to withstand considerable trauma. They are joined by the long, medium and short common ligaments, attaching to the superior and inferior plates. In the production of the compression, they are almost always left intact, the intervertebral disc seldom shows early narrowing and the compression occurs in the spongy bone. Mechanically there is no reason to suppose extensive injury of the ligaments in the compression unless the plates are fractured or an explosive comminution occurs. The usual kyphos results and often signs of cord irritation or compression are present. The laminæ are usually not fractured, the transverse articulations remain intact, and the pedicles are, as a rule, united with the inferior fragment (Fig. 2a).

Reduction utilizes the mechanical principle of leverage accomplished by hyperextension and the application of sufficient force at the fulcrum to reduce the fracture by the attendant traction on the common ligaments attached to the plates (Fig. 2b).

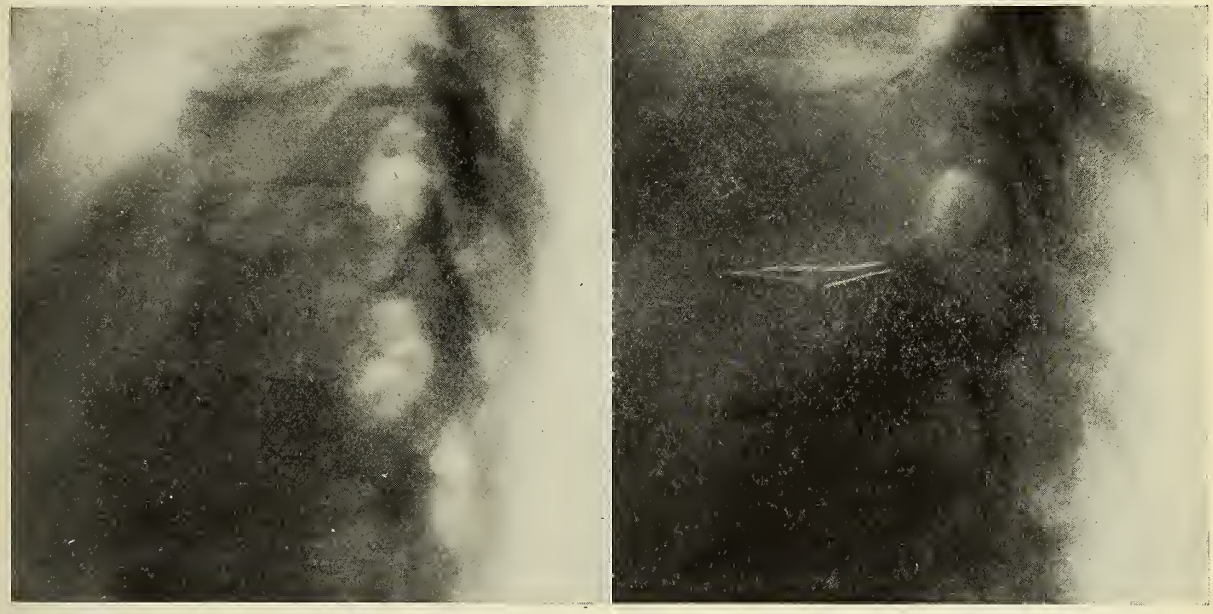

Fig. 5. Case 1. Before reduction and after reduction.

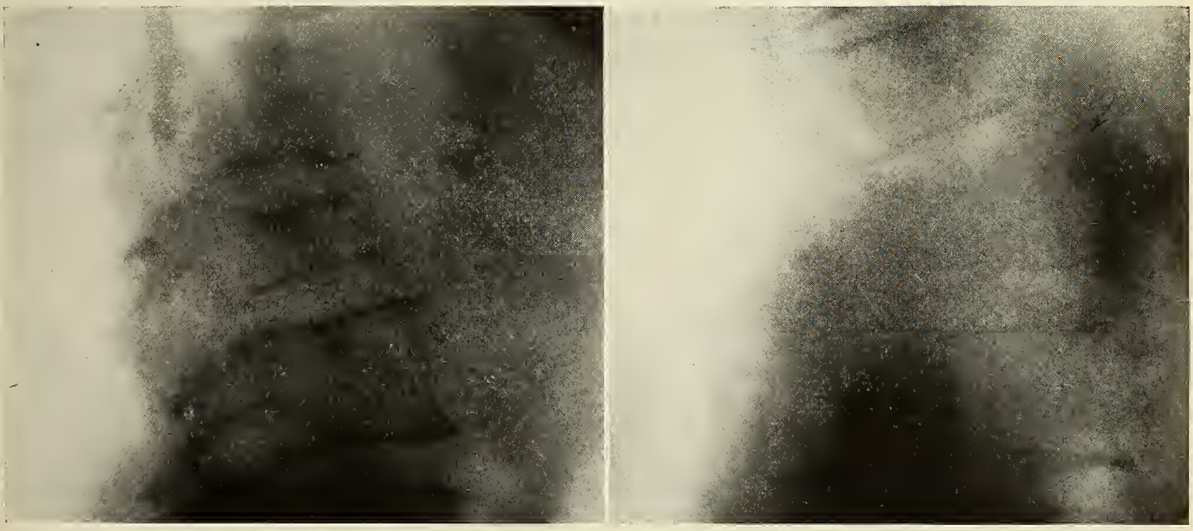

Fig. 6. Case 2. Before reduction and after reduction.

In determining this, good roentgenograms are essential. There is no need for me to urge the importance of anteroposterior and lateral roentgenograms in all back injuries. The awakening public expects them, the compensation boards demand them, and they are your insurance against malpractice action and the patient's for proper and adequate treatment.

The indicated treatment of a compression fracture of the vertebra should be the same as for any other fracture: (1) reduction adequate and immediate; (2) fixation in the reduced position until healing has occurred, and (3) the restoration of function. The case for compression fracture cannot, however, be so simply stated. A careful evaluation of the possible contraindica-

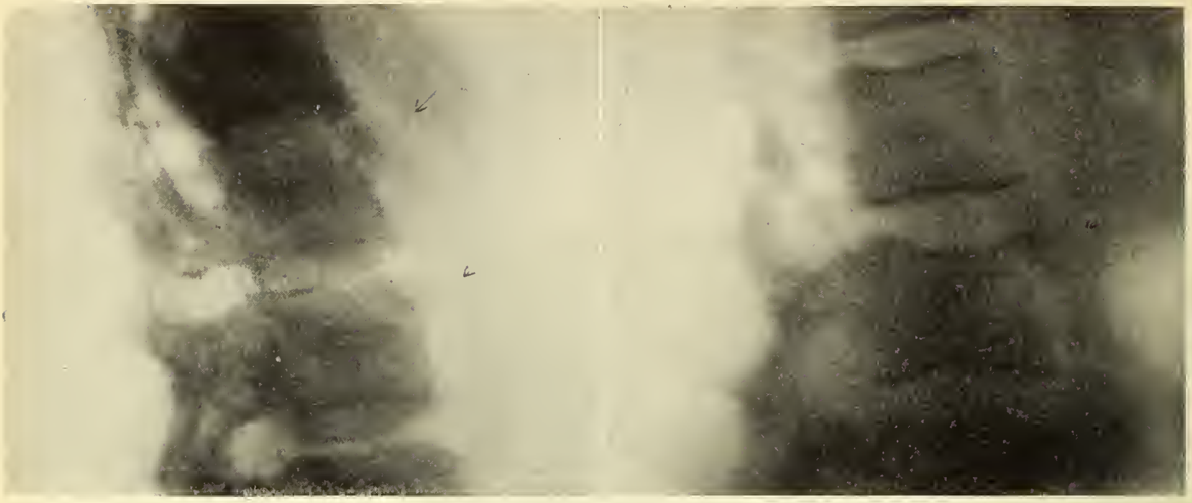

Fig. 7. Case 3. Before reduction and after reduction.

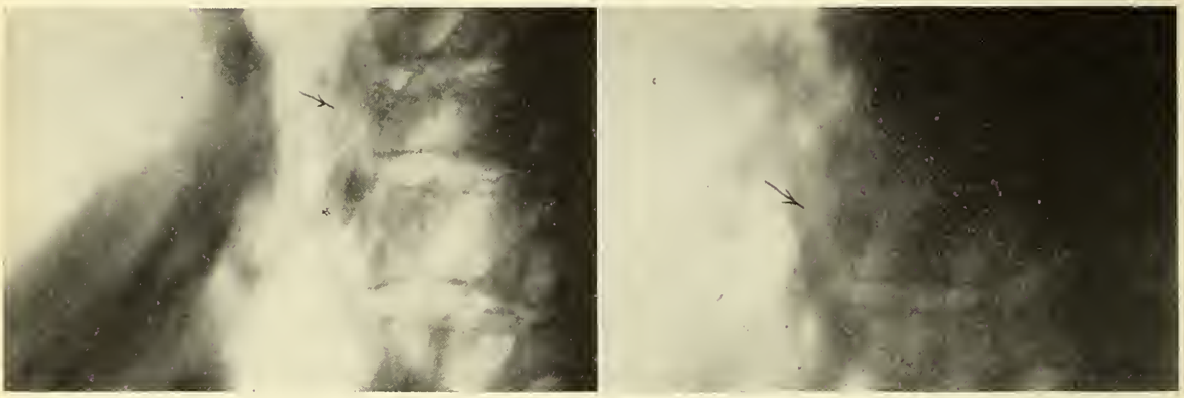

Fig. 8. Case 4. Before reduction and after reduction, showing the difficulty of fully reducing thoracic vertebra because of rigidity of the rib cage.

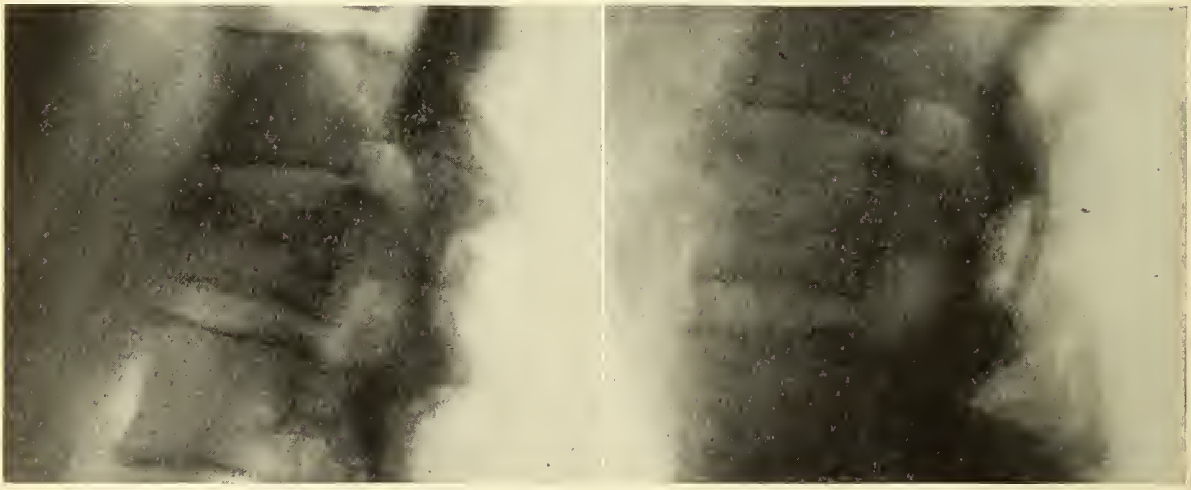

Fig. 9. Case 5. Before reduction and after reduction.

tions is essential. These may be classed as general, neurological, and anatomical. The age of the patient, together with the presence of shock or other attendant complications, might definitely contraindicate the use of this procedure, necessitating as it does prolonged confinement in a retention apparatus, although the patient may be turned frequently immediately after the application of the plaster jacket and allowed to sit up with support after the sixth week, providing that support is adequate. The judgment of the attendant surgeon must be exercised under such conditions. Remember, however, that the patient is more comfortable if the fracture is reduced and adequately supported. Neurological complications may contraindicate the use of this method because of their relatively greater importance. Thus, a laminectomy may be the first indication although, here, reduction may relieve a compression cord block and laminectomy may, in certain cases, be deferred without endangering the clinical course of the case. The paralysis may be so severe that a hopeless prognosis is evident, in which case it would be folly to subject the patient to treatment directed toward the fracture. I believe that the above are problems which must be decided in the individual cases and that the true criteria for reduction lie in the anatomical condition of the parts. If, after a study of good roentgenograms, it is evident that the neural arch of the pedicles is fractured or that there is fracture or dislocation in the region of the transverse articulations, there is obviously instability of the fulcrum and an attempted reduction by the Davis method would be quite dangerous and liable to produce further cord trauma. Here, if the apparatus is available, Rogers' method might be used to advantage. If, however, the anatomical relationships of the transverse articulations and the pedicles of the fractured vertebra and its neighboring vertebræ are normal, the possibility of cord injury during the manipulation is reduced to a minimum.

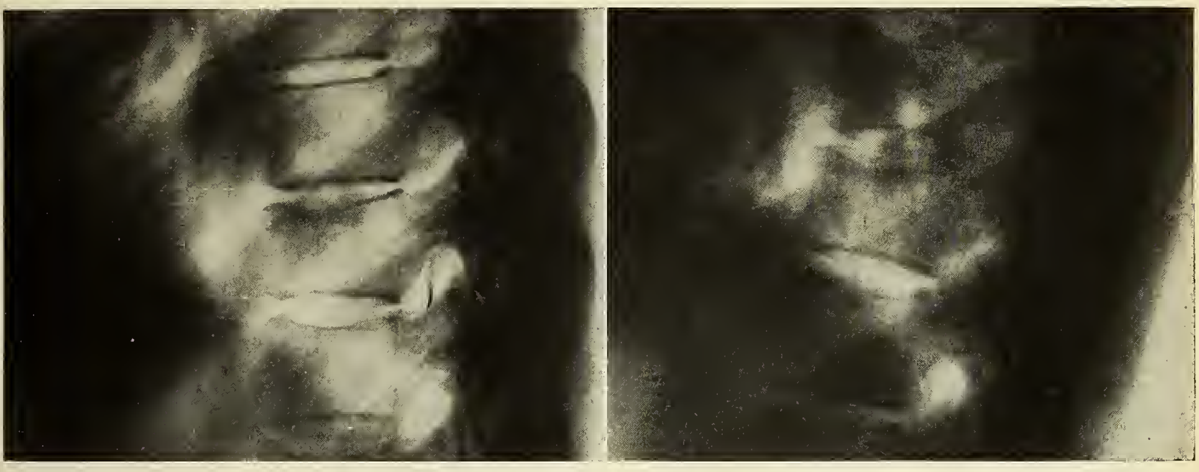

Fig. 10. Case 6. Before reduction and after reduction.

Reduction is best accomplished by putting the patient under deep anesthesia for complete relaxation and hyperextending him into a swan-dive position, by suspension of the body from the feet with the chest supported. The operator's right arm is then placed under the pelvis at the anterior superior spines (for support), and gradually increasing force is applied to the kyphos by the left hand until complete realignment is palpable (Fig. 3). A snug-fitting plaster jacket with only slight padding is immediately applied from groins to axillæ. At this point the patient may become cyanotic, due to the inverted position, and the plaster must be applied rapidly, although early use of a pharyngeal air-way usually prevents this. As soon as partial setting occurs, the suspending rope is cut, the patient supported in complete hyperextension and turned over so that the kyphos area rests on a padded pelvic support (Fig. 4).

It is not essential to include the thighs in plaster, as the ligaments hold the disimpaction if the plaster is moulded snugly to the chest and pelvis and it is here that I have modified the Davis method. In my experience there is no difficulty in obtaining the coöperation of the patient in keeping the thighs extended, rather than having them encased in plaster. The corset is worn in bed six weeks, the patient is turned frequently and allowed up in the jacket at the end of that time. At ten weeks a snug-fitting Taylor-Goldthwaite brace is applied, to be worn day and night for four to six months more, after which time it is gradually removed. The light spring steel type of brace is best, as it does not tend to produce such extreme atrophy of disuse or stiffness of the spinal muscles.

CASE REPORTS

Case 1.—D. C., male, aged 19, aviator. Compression fracture of the eleventh thoracic vertebra (Fig. 5).

Case 2.—A. S., housewife, aged 53. Compression fracture of the second lumbar vertebra, with compression spasticity. Immediate disappearance of spasticity after reduction (Fig. 6).

Case 3.—M. H., aged 34, stenographer. Compression fracture of the twelfth thoracic and first lumbar vertebræ (Fig. 7).

Case 4.—O. N., aged 46, farmer. Compression fracture of the eighth thoracic vertebra in an automobile accident. This case illustrated the difficulty of reducing thoracic vertebra compression because of the rigidity of the rib cage (Fig. 8).

Case 5.—B. G., aged 26, clerk. Compression fracture of the second lumbar vertebra from an automobile accident (Fig. 9).

Case 6.—D. B. Compression fracture of the tenth and eleventh thoracic vertebræ (Fig. 10).

Case 7.—O. P., aged 34, farmer. Fracture dislocation of the fifth and sixth thoracic vertebræ with compression of the fifth resulting from an automobile accident (Fig. 11). This patient had a subsequent laminectomy without improvement and died of ascending pyelonephrosis.

Case 8.—C. C., aged 46, steel crane operator. Comminuted compression fracture of the second lumbar and fracture of all the transverse processes. Treated by hyperextended frame after method of Rogers of Boston with complete reduction. Returned to light duty in five and a half months.

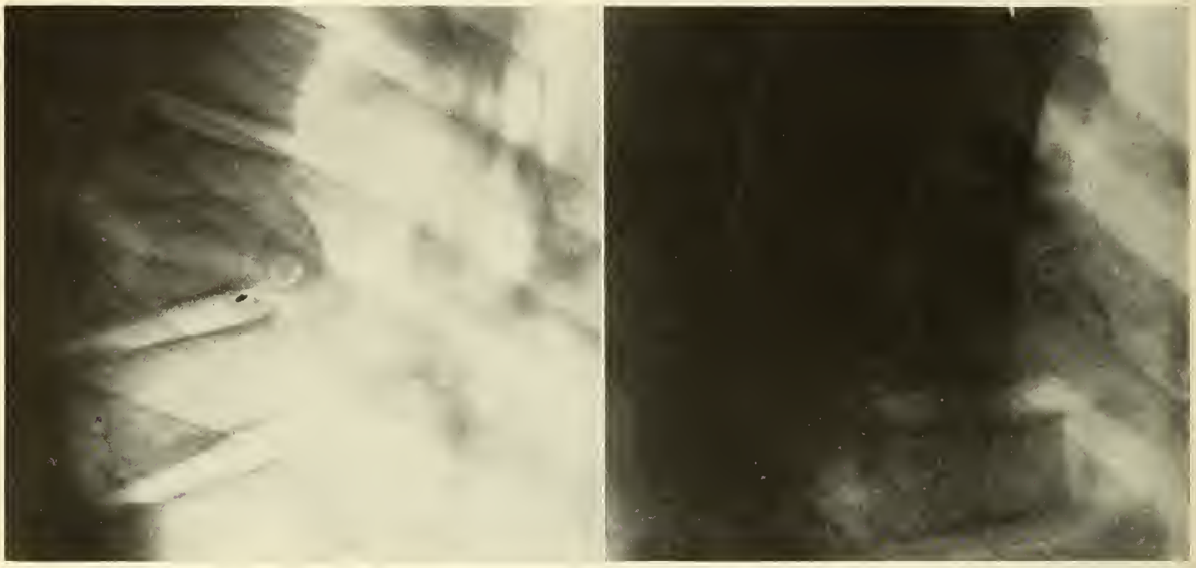

Fig. 11. Case 7. Before reduction and after partial reduction.

Case 9.—J. R., aged 35, elevator construction engineer. Compression fracture of the first lumbar vertebræ. Treated by active hyperextension with adequate reduction. Returned to light duty after the fifth month.

Case 10.—M. O'D., aged 40, nurse. Compression fracture of the twelfth thoracic and first lumbar vertebræ from an automobile accident. Treated by active hyperextension with over-correction. Returned to light duty, wearing brace, the twelfth week.

All the living patients have returned to active duty, excepting in cases 8, 9, and 10, where they are still convalescing but ambulatory with a brace. In no case has the brace been worn for more than six months. Davis reports an average disability of fourteen weeks in a series of thirteen cases but a longer period of adequate support would seem advisable to prevent recurring deformity.

FRACTURE DISLOCATIONS OF THE SPINE

There are those severe types of fractured laminæ and transverse articulations in which there is a marked dislocation of the spine.

As a student, I was fortunate enough to see the manual reduction of a dislocation of a dorsal vertebra after traction had been applied continuously for some six weeks. Four years ago while assisting Dr. Sneed at the Hospital for the Ruptured and Crippled in New York, we effected a partial reduction of a fracture dislocation of the first lumbar vertebra. Since that time, I have attempted to reduce two cases by a modification of the procedure used in New York, without definite result. Davis mentions manipulative reduction of these cases in his article, implying the use of the same method described above. Despite the fact that the results with my cases have been poor, I do not feel that, in the presence of fractured pedicles or transverse articulations, it is safe to apply hyperextension, nor to use that haphazard method recently advocated by Dunlap of Los Angeles. Figure 12 shows the method I would suggest as a procedure definitely safer and rational in its application. My failure to reduce the first two patients was due, I believe, to the fact that I over-estimated the strength of the spinal muscles in that I thought it was necessary to apply head and foot traction for four and five weeks, respectively, with resultant callus formation. I now feel that reduction should be attempted in the suitable or otherwise hopelessly unstable case as soon after the injury as possible and wish to suggest the procedure at this time.

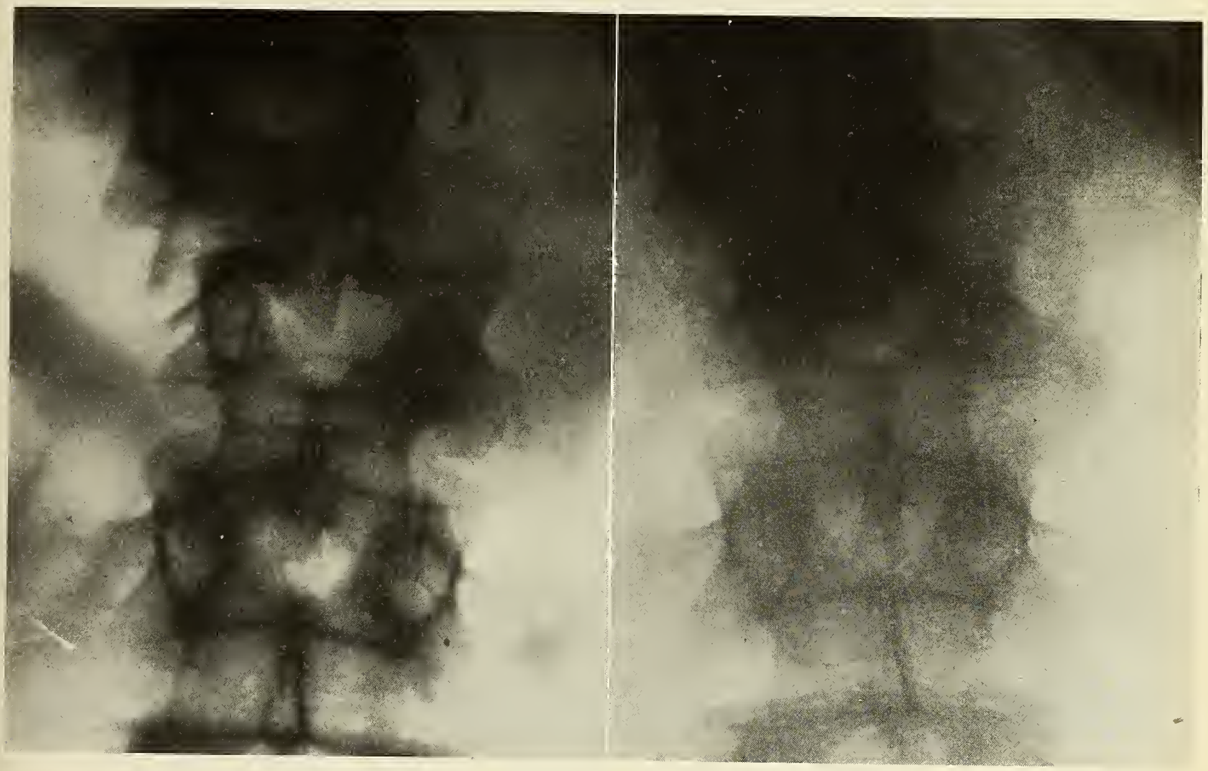

Fig. 13. Case 11. Before reduction and after partial reduction.

Case 11.—L. D., patrolman. Fracture dislocation of the second lumbar vertebra in an automobile accident. Figure 13 shows condition before and after attempted reduction with slight improvement.

CONCLUSIONS

1. The Arthur Davis method of reducing compression fractures of the spine is advocated in suitable cases as mechanically sound, a clinical improvement of economic value over older methods.

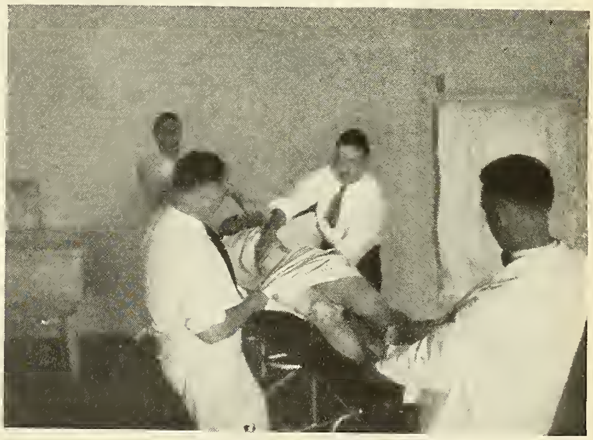

Fig. 12. Method of manipulating cases of fracture dislocation.

2. The indications and contraindications are outlined.

3. Ten further cases are added to the literature.

4. A manipulative method of treatment is suggested in severe fracture dislocations with report of two cases.

TREATMENT OF TETANUS AND GAS GANGRENE*

M. H. Manson, M.D.
Minneapolis

GAS gangrene and tetanus are both comparatively rare conditions encountered in any one surgical experience, but because of their dramatic course and high mortality deserve continued effort directed to their prophylaxis and treatment.

It is appropriate that gas gangrene and tetanus be considered together, for they have many points of similarity. The following are common to both:

1. Initiation by anaërobic, spore-forming bacilli.
2. Dependency, to some extent, on symbiosis with other organisms.
3. Result of wounds contaminated with dirt and foreign bodies.
4. Characterized by toxins, for which antitoxins have been produced which are efficient in neutralizing the toxins.
5. Accompanied by an excessively high mortality rate, approximately 50 per cent.

Their infrequent appearance complicating traumatic and operative wounds is due to the multiplicity of bacteriological and tissue factors necessary for their development, and the accepted usage and efficacy of prophylactic tetanus antitoxin. This statement may in part be challenged, in view of Wainwright's report on the 584 replies to a questionnaire on tetanus which he received from surgeons throughout the country. Of this number, only 83, or 14 per cent, employed prophylactic antitetanus serum as a routine procedure. However, these represent an industrial group and, as it has been pointed out that 80 per cent of the entire incidence of tetanus arises in uncontrollable circumstances such as wounds contaminated with debris or soil from the street, garden, stable, and farm, the use of anti-tetanus serum in this state is probably more prevalent.

INCIDENCE

The frequency of tetanus in civil practice is difficult to determine, but the incidence in wartime is interesting and demonstrates again the value of antitoxin. Cornwall, 1917 (New York Medical Journal) gives the following statistics:

	Wounded	Cases	Per 1,000
Crimean War	12,092 (English)	9	1.5
American Civil War	217,000	505	2.0
Franco-Prussian War	95,000	350	3.5
World War	27,677 (German)	174	6.6

thus showing an apparent increase.

These are undoubtedly figures for the early part of the World War. The incidence of tetanus in the British Army in October, 1914, was 32 per 1,000, and after the universal use of antitetanic sera the ratio was cut down to 2 per 1,000. The good fortune of the United States in profiting by the experience of the Allies is exemplified in the ratio of 0.014 cases of tetanus per 1,000 battle injuries—only 36 cases associated with 176,132 injuries.

MORTALITY

That the mortality in tetanus varies inversely to the incubation period is well known. A long incubation period goes hand in hand with a low mortality. Prophylactic injections of antitoxin prolong the incubation period, as shown in the following:

During the war in 1914-15, the average incubation period was 13.4 days; in 1915-16, 31.2 days, and in 1917-18, 46.19 days. With the progression of the war, there was an increase in multiple injections of antitoxin.

The mortality of established tetanus is from 40 to 70 per cent. The virulence of the organism influenced by season and location, the incubation period, the site of the injury and the treatment are all factors determining the death rate.

PROGNOSIS

The prognosis, as judged from the mortality rate, must be very guarded. The best prognosis is offered when the incubation period is long; arbitrarily, longer than 10 days; when the wound is farther away from the central nervous system; when prophylactic tetanus antitoxin has been given; and when the antitoxin is given early after the onset of symptoms. Stone believes that if the trismus progresses rapidly and is complete in twenty-four hours, the prognosis is twice as grave as when the trismus is tardy in appearance or incomplete. Calvin and Goldberg have recently published an excellent paper in which they evaluate the prognosis in tetanus and point out the importance of prophylatic antitoxin administration.

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 14, 1930. From the Department of Surgery, University of Minnesota.

The cause of death is exhaustion or cardiac failure from long continued or severe clonic convulsions or respiratory failure due to spasm of the glottis or diaphragm.

ROUTE OF TOXIN

The method of transit of the toxin from a local wound to the cells of the spinal cord is by way of the motor nerves. Meyer and Ransom (1903) have shown that the toxin is picked up by the end plates in the muscle, and travels by way of the axis cylinders. Aschoff and Robertson believe that the toxin travels by way of the perineural lymph spaces. In either event, the toxin is not picked up by the cells of the central nervous system from the blood, and it is generally accepted that after the toxin has combined with nerve cells, the antitoxin is not capable of neutralizing it, a fact which demands the earliest possible administration.

TREATMENT:

The treatment of tetanus resolves itself into

1. Neutralization of the toxins present.
2. Relaxation of muscles—prevention of tetanic spasms.
3. Prevention of further absorption of toxins by removal of its source as much as possible.

1. *Antitoxin.*—The first thought should be antitoxin administration. Its merit has been unquestionably demonstrated. Irons collected 252 cases with a total mortality of 71 per cent. There were 142 treated without antitoxin, with a mortality of 77 per cent. In those treated with antitoxin, the mortality was 63 per cent. If the cases given antitoxin are divided into those who received small doses and those who received large doses, the mortality was 70.47 per cent in the former, and 51 per cent in the latter. Mathier reported 960 cases with antitoxin treatment, with a mortality of 38.8 per cent. He also reported 40 cases without antitoxin treatment, with a mortality of 80 per cent. Permien reported 330 cases with antitoxin treatment, with a mortality of 57.7 per cent, and in those cases without this treatment the mortality was 78.9 per cent. The reasons for failures in the use of antitoxin are: (1) late administration; and (2) inadequate dosage.

The route of administration has been the subject of much controversy. Wainwright cites some impressive statistics to show that the mortality is increased by intraspinal therapy. Freedlander, Dean, and others advocate intravenous therapy in preference to intraspinal. On the contrary, Astley Cooper Ashhurst, using the same arguments, strongly urges intraspinal administration of serum. In Bruce's comprehensive analysis of 1,458 British cases, it is seen that no conclusions can be drawn from one method of therapy, for there is such a variance of mortality rates. It is felt that all routes of administration should be used—subcutaneous, intramuscular, intravenous and intraspinal, the most important of which is the intravenous route.

The initial injection of antitoxin should be preceded by 0.5 c.c. subcutaneous. If a painful, urticarial wheal results, desensitization may be carried out as follows: a 1-10 dilution is made by taking 1/10 c.c. of the antitetanic serum and diluting with salt solution to 1 c.c. Subcutaneous injections are made every 15 minutes.

First injection—¼ c.c. of 1-10 dilution.
Second injection—½ c.c. of 1-10 dilution.
Third injection—0.1 c.c. of undiluted serum.
Fourth injection—0.5 c.c. of undiluted serum.
Fifth injection—1.0 c.c. of undiluted serum.

In half or three-quarters of an hour, the remainder of the antitoxin may be given.

At least 100,000 units of antitoxin should be given an adult within the first twenty-four hours. The dosage may be divided as follows: 60,000 units intravenously in three doses, 20,000 intramuscularly and 20,000 intraspinally. The intraspinal administration has one qualification. Everyone who has treated tetanus knows the importance of minimizing external stimuli, and how peripheral irritation may precipitate increased muscular spasms. It is possible that in our anxiety to give the antitoxin intraspinally, this fact is forgotten. The patient should be well protected with sedatives and soporifics to eliminate as far as possible the stimuli which accompany the changing of posture, the preparation and the introduction of the needle in making the spinal puncture. If the patient is not so fortified, the spinal administration should not be attempted. In view of the evidence which casts doubt upon the efficacy of intraspinal administration of antitoxin this method of treatment is not urged. On the second and third days, the total dosage should be at least 75,000 units each day, the majority preferably given intravenously. The administration of antitoxin should be continued for seven days, employing decreasing doses and increasing intramuscular proportions. Because absorption is slowest from the subcutaneous tissues, the dosage in the last few days should be given by that route.

The total dose should be not less than 300,000 to 350,000 units. Freedlander gave a total of 755,000 units to one patient, practically all intravenously. The danger of anaphylaxis has been overestimated. In England alone, during the World War, some two millions of prophylactic doses of antitetanic serum were given, out of which huge number only eleven cases of shock were reported.

In the event of the appearance of an anaphylactic reaction, 1 c.c. of adrenalin or ephedrin may be given. It has been demonstrated that ether anethesia protects against anaphylactic reactions. If there is a wound necessitating operative interference and ether is used, the antitoxin should be given at this time.

2. *Symptomatic.*—The protection of the patient from external stimuli needs more consideration. When a patient with tetanus is first seen, all routine procedures which are time-consuming and which expose the patient to needless irritation should be omitted. He should receive his first antitetanic serum and be immediately transferred to a single, quiet, darkened room. Chloral hydrate is the most useful of the hypnotics, and is best given by rectum, either with olive oil, which retards absorption somewhat and prolongs its action, or with tap water. Rectal administration of sedatives and anesthetic agents is preferable to the oral route, because of the trismus, and especially for chloral, because of its somewhat unpleasant taste, gastric irritation, and because it is absorbed best from the rectum. The dose is 30-45 gr. repeated every four hours as necessary. Rectal ether has been used, but repeated doses lead to considerable irritation. German authors have reported favorable results with avertin (tribromethylalcohol), which is non-irritating and does not usually produce the excitement often seen with ether. The dose is 80 mg. per kilogram of body weight.

Novocain injection of the muscles of mastication for the relief of trismus, the injection of the phrenics to alleviate or obviate diaphragmatic spasm and similar procedures may have a place in selected instances.

The use of magnesium sulphate is heroic treatment and should be reserved for those cases in which there are severe and prolonged convulsions. Its temporary effectiveness weighed against the dangers of respiratory paralysis should be carefully considered before it is used. In critical cases, it is most efficaciously given intravenously. A 3 per cent solution is injected at the rate of 5 or 6 c.c. a minute, carefully watching the respiration. If any symptoms of respiratory failure should manifest themselves, 2.5 per cent calcium chloride is immediately given intravenously until such symptoms have subsided. The calcium chloride should always be in a syringe ready for use before the injection of magnesium sulphate is started.*

3. *Wound.*—Treatment of the local wound should be effective and have as its basis the removal of all devitalized tissue and foreign bodies, followed by irrigation or application of antiseptic and oxidizing agents, preferably Dakin's solution. Antitetanic serum is injected proximal and near to the wound.

CHRONIC AND LOCAL TETANUS

Other forms of tetanus occur, but are not accompanied by the high mortality and urgency of treatment as tetanus following within ten or fifteen days of the receipt of a wound. In those who have been given antitoxin as a preventive, there may be anomalous forms. Local tetanus may be limited to groups of muscles or to an extremity. Treatment consists of attention to the wound in the proper manner, and the administration of antitetanic serum. Chronic tetanus and idiopathic tetanus may follow trivial and overlooked wounds. The symptoms appear late, even months after the injury. The patient is often afebrile, with spasmodic contractions of limited groups of muscles, rarely generalized; the characteristic convulsions do not occur. The prognosis is good.

The following case in a child illustrates the treatment of tetanus with a short incubation period.

---

*The intraspinal administration of magnesium sulphate is mentioned only to be deprecated. There is no adequate means of combating respiratory failure, for calcium chloride is of no avail. Its use subcutaneously and intramuscularly is of no value for acute symptoms, but may be an aid in depressing motor activity.

Subcutaneously 1.5 c.c. of a 25 per cent solution per kilogram of body weight may be given three or four times daily. Intramuscularly 0.6 c.c. of the same solution per kilogram may be given five or six times daily.

CASE REPORT

C. L. O., a girl of eight years, had been injured on the posterior aspect of the thighs by a manure spreader, five days prior to admission. The wound had been cleansed with lysol and iodine after the injury, but no tetanus antitoxin was given. The symptoms made their appearance about eight hours prior to admission, the initial symptoms being pain and difficulty in opening the jaws. On admission, the child had a temperature of 100.2°, pulse 105. There was trismus III, opisthotonos I, neck rigidity I, spasticity of the right lower extremity IV. On the posterior upper third of the right thigh, there was a lacerated wound about 4 cm. in length and a similar smaller wound on the left thigh. Both were draining a seropurulent exudate. The history was inquired into with regard to asthma, hay fever, or previous serum injections. In spite of this being negative, 1 c.c. of tetanus antitoxin was given subcutaneously and after twenty minutes of observation, 10,000 units of tetanus antitoxin was given intravenously and 10,000 intramuscularly. The child was taken to the operating room and, under ethylene anesthesia, the wounds were opened widely, all discoverable necrotic tissue removed and Dakin's tubes inserted. Antitoxin (2,500 units) was injected about each wound, thus making a total of 25,000 units of antitoxin on the evening of admission.

Upon being returned to her room, the patient was given 30 gr. of chloral hydrate by rectal route, which was effective in combating the extreme restlessness and diminishing the clonic spasms of the right lower extremity.

Tetanus antitoxin was given for the following ten days by the intravenous and intramuscular route in doses of 10,000 units and subsequently by the intramuscular and subcutaneous route only. The total dosage was 115,000 units, given over a period of ten days. The child continued to be irritable and restless, but took fluid well by mouth except during the first two days, when the fluid intake was maintained by hypodermoclysis of 5 per cent glucose solution. Choral hydrate was continued for thirteen days in 30 gr. doses, making a total of 1,110 gr. or 71.6 gm. Luminal was also used to increase the intervals of chloral administration. The fluid intake averaged 1,500 c.c. and the caloric intake averaged 1,400 calories each day. At the end of the twelfth day all the symptoms had disappeared except the restlessness, irritability and spasticity of the right lower extremity. The wounds on the thighs which had been irrigated with Dakin's solution, followed Dakin's packs and finally dry dressings, were now practically healed. The child was up in a chair on the fourteenth day and was discharged on the thirtieth day with no complaint.*

GAS GANGRENE

Unlike tetanus, which was recognized in ancient times, the first case of gas gangrene was described in 1853, but it was not until the late war that our knowledge of its course and treatment was anything but fragmentary. Interest in the subject was stimulated by five cases occurring at the University Hospital in the past year and a half.

Gas gangrene may be defined as a spreading, moist gangrene produced by gas-forming anaërobic bacteria in extensively traumatized tissues. It is characterized by a gaseous infiltration and edema of the part affected, and by change in the color and contractibility of the muscle. Its pathology is essentially that of devitalized muscle. The causative organisms may rightfully be confused in our minds, for they have been given many synonymous appellations. In an attempt to clarify these, and assign a standard nomenclature, the following table is given:

ETIOLOGY

1. Clostridium Welchii—80-90%.
    - B. Welchii—Welch & Nuttal, 1892.
    - B. Aerogenes capsulatus—Fraenkel, 1893.
    - B. Perfringens—Veillon & Zuber, 1898.
    - B. Phlegmonis emphysematosæ—Frankel.
2. Clostridium edematis maligni (Septique)—10-15%.
    - Vibrion septique—Pasteur, 1876.
    - B. Edematis maligni—Koch & Gaffky, 1881.
    - B. of Ghons & Sachs—I.
3. Clostridium Novyi—5-6%.
    - B. Edematiens—Weinberg & Sequin, 1915.
    - B. Bellanosis—Weinberg & Sequin.
    - B. Edematis maligni II—Novy, 1894.
4. Clostridium histolyticum.
    - B. Histolyticus—Weinberg & Sequin.

One or more of the above organisms are usually associated with *Bacillus sporogenes*, *Bacillus proteus* and various streptococci or staphylococci. *Bacillus sporogenes* associated with *Clostridium welchii* enhances its virulence four to five times, as do certain streptococci. *Clostridium welchii* and *Clostridium novyi* mutually stimulate activity.

The average incubation is three to five days.

COURSE

We may picture the progress of a typical case somewhat as follows: Given a wound with intensive muscle damage at a distance from the surface, and the introduction of one or more of the pathogenic gas-producing anaërobes, usually with other organisms. The histological picture of the disintegrated muscle and the tract of an offending instrument closely resembles a freshly made beef emulsion, and makes an ideal culture medium for this group of bacteria. The lack of definite lymphatics within a mass of skeletal muscle makes the whole muscle bundle a lymph space, and with the trauma this is broken, thus constituting the first break in the circulation. With the edema resulting from the injury and the toxins produced by the growth of the organisms, there is further muscle destruction and hemolysis of the blood clot, thus constituting a vicious cycle. Gas is now formed and forces itself up and down the muscle bundle, opening up new paths for the toxin and disseminating bacteria. The organisms have appeared halfway up the anterior abdominal wall in three and a half hours after injection into the thigh of a rabbit. That the gas has sufficient force to do this may well be visualized when we consider the experiment of Taylor. He connected an autoclave gauge by means of a rubber tube, to a culture tube of dextrose broth inoculated with *Clostridium Welchii.* Within two hours, the pressure began to rise and in six hours it had reached a pressure of twenty-three pounds and blew off the tube. I have obtained pressures of 30 pounds in twenty-four hours incubation.

---

*Prof. F. DeQuervain, who has had very large experience with tetanus, has never seen an adult with established tetanus recover, in whom the incubation period was less than 8 days; recovery following tetanus in children with incubation periods of such lengths however does occur.[27]

The pressure increases, the lymphatics are occluded, producing more edema, finally leading to venous obstruction. At this point, the muscle degenerates from lack of nutrition, and with the circulation so impaired, a fresh supply of leukoytes is denied the site, and the infection progresses rapidly. The mechanics of this entire vicious cycle is so pyramided that an infection may be well advanced in two hours and death from massive gangrene of an entire limb can occur in less than thirty hours.

DIAGNOSIS

The history is of importance only in that it may strengthen the suspicion that certain types of wounds may be contaminated by gas bacilli. As in tetanus, any wound contaminated by bits of clothing and dirt makes gas gangrene a potentiality.

Pain is an early symptom and is out of proportion to the severity of the injury. Many patients will complain of their dressings being too tight and ask to have them loosened. Upon removing the dressing, the characteristic odor, the gun-metal, bluish discoloration, the reddish brown discharge, blebs of the skin and gas in the tissues make the diagnosis certain. The gas may be palpated as crepitation; may be heard as fine crackling, explosive sounds with a stethoscope, or may be seen by *x*-ray examination in the soft tissues.

INCIDENCE

The incidence in the U. S. Army during the World War was as follows: Of 128,265 wounds of the soft parts, 1,389 or 1.08 per cent were complicated by gas gangrene, and of 25,272 wounds complicated by bone fractures, 1,329 or 6.26 per cent developed gas gangrene. The extremities were involved in over 80 per cent; nearly one-third of the cases were of the leg.

MORTALITY

In 5,449 cases collected from the literature, the average mortality is 38.5 per cent. The death rate varies from 15 to 60 per cent, as given by different authors.

PROGNOSIS

The relation between incubation period and prognosis, although not as definite as in tetanus, has some significance. In general, the longer the interval between the probable inoculation of organisms and the onset of symptoms, the less virulent will be the infection. There is no method of predetermining when an infection is going to be of a fulminating or a localized type. The two factors which ultimately determine prognosis and mortality are the virulence of the infection and the resistance of the individual, for neither of which we have an adequate measure.

The cause of death in gas gangrene is usually the overwhelming toxemia as a combined result of the toxins produced by the anaërobes and protrolytic destruction of tissue. Sudden deaths have been attributed to embolism from the gas.

TREATMENT

As a basis for treatment, we may divide the cases into two groups for convenience of description: (1) virulent or massive gas gangrenes; (2) avirulent or localized.

PROPHYLACTIC

Prophylactically, the possibilities of the development of gas gangrene must be kept in mind. A thorough debridement should be done on any wound with such potentialities and prophylactic polyanaërobic antitoxin should be given intramuscularly in doses of 20-30 c.c.*

---

*This serum may be obtained from several of the biological and pharmaceutical supply companies (Lederle, Mulford, Cutter). The cost averages about $10.00 for 100 c.c. In one serum, the proportions are tetanus antitoxin, 100 u., and antitoxin for the toxin produced by *Clostridium Welchii,* 15 u., *Clostridium edematis maligni,* 300 u. (*Vibrion septique*) and *Clostridium histolyticum,* 200 u. in each c.c. of serum. The antitoxin for *Clostridium welchii* alone (Perfringens antitoxin—Mulford) is somewhat less in cost, due to its use in intestinal obstruction, a use which is apparently unwarranted. (The average cost for tetanus antitoxin is $1.50 for 1,500 u. for prophylactic use, and $6.00 for 10,000 units for therapeutic use.)

THERAPEUTIC

In virulent gas gangrene, when an entire extremity is involved, amputation by the transfixion method should be performed. No tourniquet should be used. If of a lower extremity, the anesthesia of choice is spinal.

All muscles should be carefully inspected, and any that present brownish discoloration, do not contract when pinched, or do not bleed freely, should be excised until healthy muscle is encountered. The wound is left open and dressed lightly.

Transfusion of whole blood may be a life-saving measure in combating shock following debridement or amputation. Its value is further enhanced by the fact that there is often an acute secondary anemia produced by the hemolytic toxin elaborated by *Clostridium welchii.*

Secondary suture may be done after three to four days, depending upon the local condition. Of the various antiseptic and oxidizing agents that have been advocated, Dakin's solution is the one of choice.

In localized or avirulent gangrene, complete excision of the affected muscle may suffice, taking advantage of the fact that the infection progresses in the direction of the muscle bundle and is limited by the fascial compartments. Drummonds and Neligan, Ivens, and Kellogg Speed have reported good results in this type of case. The criteria for resection are color, contractibility and bleeding.

The status of .polyvalent anti-gas gangrene sera has been somewhat confused by the varying reports from the late war. The French developed a potent antitoxin and were enthusiastic; the British and Americans were rather late in adopting it, and their experience was not extensive enough to warrant adequate conclusions; the German antisera was of very low antitoxin titre, which accounts for their poor results. The following shows that potent antitoxin is worthy of use:

Sacquepee gave antitoxin to 319 wounded men with a resulting incidence of gas gangrene of 1.17 per cent. In a control series the incidence was 7.2 per cent. In a series of 191 developed cases, the mortality in those treated with polyanaërobic antitoxin was 13.9 per cent, while in the same region the untreated cases showed a mortality of 75 per cent. Ivens gave a polyanaërobic antitoxin to 433 cases in which there were 30 cases of gas gangrene when first seen. In this series there was one death.

Numerous American authors have recently encouraged its use (Kling, Morris, Gage, Baldwin and Gilman, Larson and Pulford and others). Experimentally, the antitoxin that is available today is efficient in neutralizing the toxins produced by the pathogenic anaërobes (Kling). The dose should be on an average of 100 c.c. for two or three days, given intravenously and intramuscularly near the wound.

CASE REPORT—GAS GANGRENE

P. M., aged 30, was admitted December 12, 1929. At 9:30 on the morning of December 9, the patient sustained a shotgun wound to the right leg and thigh. On the evening of December 10, about thirty-six hours after the onset of the injury, bluish discoloration of the foot and ankle was noted by the attending physician. Fifteen hundred units of tetanus antitoxin were administered. During the following day, the gangrenous process extended to the knee.

At the time of admission, at 1:00 a. m. on December 12, the entire right leg was gangrenous. The thigh was very edematous, the skin of the lower third was of a gun-metal color with many blebs and the characteristic odor of gas gangrene. Crepitation was palpable on the medial aspect of the thigh, extending up to the perineum. The temperature was 102°, pulse 130; the patient was disoriented and acutely ill. The blood pressure was 108/70. The hemoglobin was 67 per cent; R. B. C. 3,030,000, W. B. C. 17,450, of which 92 per cent were P.M.N.s.

Forty c.c. of perfringens antitoxin were given intravenously and the patient was taken to the operating room within an hour after admission. He experienced a rather severe chill following the intravenous antitoxin and the operation was delayed about thirty minutes. Under spinal anesthesia, the right thigh was amputated as high as possible. Although the incision was made just below the inguinal ligament, gas was encountered and the muscles on the medial side were dark in color and non-contractile. Debridement was done, necessitating excision up to the inferior spine of the pubic bone. One hundred fifty c.c. of perifringens antitoxin was injected into the stump, which was left open and a light dressing applied.

The patient continued to be critically ill, was irrational and very agitated, the temperature varying from 101 to 104 degrees. On the following morning, 45 c.c. of perifringens antitoxin was given intramuscularly, and the patient transfused with 500 c.c. of whole blood by the semi-direct paraffin-tube method. Dakin's packs were applied to the amputation stump. On the third day, 40 c.c. of perifringens antitoxin was again given intramuscularly. No further evidence of gas gangrene was seen, and after a very stormy time for about a week, rapid improvement was apparent.

Skin traction was applied to the stump and Dakin's packs continued. On January 10, after subcutaneous desensitization, 25 c.c. of perifringens antitoxin was injected into the muscles of the stump and under spinal anesthesia the remaining portion of the femur was disarticulated, the skin undermined for a distance, and traction again applied. Subsequent implantation grafts were done on the stump, and at the time of discharge epithelialization was practically complete.

The reason for giving the antitoxin prior to the second operation was because of the well known ability of spores of *Clostridium welchii* to be dormant in tissues, especially when sequestra are present. With further trauma or any procedure diminishing the resistance of the part, gas gangrene may again result. The same is true of tetanus.

Because of two cases of virulent gas gangrene following amputations in which there were chronic ulcers in the affected extremity, we have been culturing chronic ulcers of all types and find the presence of pathogenic gas-producing anaërobes a not infrequent occurrence. Prophylactic polyanaërobic antitoxin should be given prior to amputation or other operative procedure in such cases.

SUMMARY

Tetanus and gas gangrene have many points of similarity, and should be thought of simultaneously as a potentiality in any wound contaminated by soil, clothing and other foreign material. The diagnostic membrane in diphtheria corresponds to the dirt and foreign body, and as diphtheria antitoxin is given on seeing the membrane, so should antitetanic serum be given when there is dirt in a wound (MacConkey). In especially suspicious cases, polyanaërobic antitoxin should be given. The first thought in treatment of tetanus should be adequate administration of concentrated antitetanic serum. Adequate dosage is large dosage for the first days of the symptoms. The preferable route is intravenously. Elimination of peripheral irritation and external stimuli is best accomplished by rectal administration of sedatives and anesthetic agents. Further absorption of toxin is prevented by debridement of the wound and institution of antiseptic and oxidizing agents, preferably Dakin's.

Gas gangrene is the result of a multiplicity of bacteriological and tissue factors and the progress of the infection is a result of the operation of several vicious cycles.

The basis of treatment in gas gangrene is the breaking of the vicious cycles, accomplished by (1) the elimination of the entire part involved or excision if localized; (2) wide exposure, thus eliminating as much as possible anaërobic conditions; and (3) administration of antitoxin. Transfusion of whole blood may be a determining factor in recovery. The presence of gas-producing, pathogenic anaërobes in chronic ulcers makes gas gangrene a possible complication of any surgical procedure directed to their removal, and the surgeon must be prepared to prevent or treat this complication.

HEALTH CONDITIONS IN THE UNITED STATES

In a report recently made public by the United States Public Health Service, Surgeon General H. S. Cumming points out that for the past fiscal year health conditions throughout the United States were generally good, with the exception of certain diseases. The prevalence of influenza and pneumonia was comparatively low during the year, and there were comparatively few deaths from these conditions.

Yellow fever did not appear in the United States or its possessions during the year. Gratifying progress has been made in the control of this disease, which has not appeared in epidemic form in the United States since 1905, but the presence of yellow fever in Brazil and Colombia in South America during the year showed that its introduction into the United States is possible, and the mosquito which spreads the disease is known to abound in certain areas in this country.

Plague-infected rodents were found in the State of California, but no human cases were found in the United States or its possessions. Cases are likely to occur, however, as long as the infection exists in rodents. Plague was reported in many of the ports with which the United States has commerce. It was present during the year in all the grand divisions of the world, with the exception of Australia.

Preliminary figures show a decrease in both the birth and death rate as compared with the preceding year. This is a continuation of the trend which has been noted in the statistics for most civilized countries for several decades.

In 1928 there was an increase in the incidence of malaria. This disease has been disappearing from many parts of the United States where it was once prevalent. For 1929 the reports from 45 states showed a slight decrease in malaria deaths from the high figures of 1928, but in some of the southern states where malaria is a serious problem, the reports of cases and deaths show increased prevalence in 1929 as compared with 1928.

The case and death rates for diphtheria have been decreasing for many years, and in the calendar year 1929 these rates reached new low records. Forty-five states reported 71.4 cases of diphtheria and 6.6 deaths per 100,000 population. Ten years ago, in 1919, 37 states reported 137 cases of diphtheria per 100,000 population, and the diphtheria death rate in 32 states was 13 per 100,000. These were low rates at that time, but the 1929 rates are nearly 50 per cent lower. There is no doubt that the use of antitoxin and immunization against diphtheria has contributed to the remarkable decline in the number of diphtheria cases and deaths. If these agencies had been more generally used, the improvement would have been greater.

The incidence of meningococcus meningitis has steadily increased since 1924 to the winter of 1930. But in the spring of 1930, the number of cases dropped below the figures for 1929.

The prevalence of pellagra has been increasing for several years. In 1924 the pellagra death rate computed from reports to the Public Health Service was 2.5 per 100,000 population. The rate rose steadily until 1928, when it was 5.7 per 100,000 (based on reports from 45 states). For the calendar year 1929 the pellagra death rate was 5.5 per 100,000 population.

During the calendar year 1929, the incidence of infantile paralysis was lower than it had been since 1926, but by the end of June, 1930, there was a marked increase in the number of cases reported. Reports of unusual prevalence of this condition were received from communities in widely separated parts of the United States. This disease normally reaches its greatest incidence in this country in the late summer and early fall.

For three years, at least, the incidence of smallpox in the United States has been increasing. Forty-five states reported 34,685 cases of smallpox in 1927, 38,114 cases in 1928 and 41,458 cases in 1929. The disease was of the mild type and in the 45 states only 442 deaths were recorded during the three years; yet, the 114,000 cases of smallpox represent an incalculable amount of suffering and a large economic loss to the country, all of which could have been avoided by vaccination and revaccination. One danger in smallpox lies in the fact that the virulent type of the disease may appear at any time in a community not protected by vaccination, and before the disease can be checked it may take many lives.

Low records were also reported during the year 1929 for tuberculosis and typhoid fever.

Nine hundred seventy-five cases of undulant (Malta) fever were reported to the Public Health Service for the calendar year 1929, with 41 deaths. The importance of undulant fever becomes more apparent as more is learned of the disease.

Tularemia is much more widespread than it was thought to be when the disease was discovered. The reports are not complete, but in 1929, 461 cases and 36 deaths were reported to the Public Health Service.

The mild type of typhus fever, which differs in some respects from the Old World typhus and from the form of typhus which is endemic in Mexico, was reported during the year 1929 in a number of states, especially in the southeastern part of the United States. Incomplete reports showed 239 cases of typhus fever and 16 deaths from this disease in 18 states during 1929. —*Health News*, U. S. Public Health Service, January 4, 1931.

ACUTE TRAUMATIC SURGERY OF THE ABDOMEN*

Karl Meyer, M.D.
Chicago

With the ever increasing number of automobile accidents the early diagnosis and adequate treatment of non-penetrating injury to the abdomen is assuming greater importance. It is important to determine whether an individual who has received a blow to his abdomen is suffering from a simple contusion requiring conservative treatment, or whether he has a severe intra-abdominal injury demanding operative intervention. Exploration of every case is unwarranted, because an unnecessary operation may deprive the individual of his chance of life. Operative interference is most effective when instituted before the symptoms of visceral injury are immutably present.

I have recently reviewed the records of ninety-four non-penetrating injuries treated on our service at the Cook County Hospital in which the diagnosis was confirmed by operation or autopsy. In kidney injuries the presence of hematuria was accepted as evidence of injury to the kidney or bladder.

This series shows evidence of kidney injury in thirty-three cases, liver in twenty-three, spleen in fourteen, bladder in fourteen, intestine in ten, gall-bladder in two, mesentery in one, and epigastric vessels in two.

Evidence of kidney injury was present more frequently than that of any other organ. The high incidence of kidney injury is explained by the fact that the presence of hematuria, which occurs in about 95 per cent of cases of trauma to the kidney, enables us to diagnose slight degrees of kidney injury that would otherwise go on to spontaneous repair unnoticed.

The most common cause of injury was direct violence over the kidney area. Indirect violence such as a fall on a portion of the body remote from the kidney, and violence from muscular effort, as, for example, in preventing a fall, were less common. Kust, in attempting to explain the mechanism of kidney injury, showed experimentally that the violence causes a sudden increase in the intrarenal hydrostatic pressure with resultant rupture of the tubules. The line of rupture extends radially from the pelvis. The extent of injury may vary from a partial to complete rupture of the kidney parenchyma, avulsion of the pedicle or pelvis, or rupture of the peritoneum overlying the kidney with extravasation of blood and urine into the peritoneal cavity.

In this series the right kidney was injured in nineteen cases and the left in fourteen cases. The right kidney is anatomically more or less fixed by the liver, so that it cannot escape an impact. The left kidney, however, is mobile and may be displaced instead of injured by a blow.

Hematuria is the most common finding associated with injury to the renal parenchyma. Blood is usually present in the first voiding, but it may be delayed from two to three days. Hematuria may be absent in avulsion injuries of the kidney pedicle, pelvis or ureter.

Pain over the renal area is usually moderate and constant, but it may be severe and sometimes simulates renal colic.

Extravasation of blood and urine from renal injury may manifest itself in several ways. There may be a tumor mass in the kidney area, or the swelling may extend into the groin. Spasm of the lumbar muscles may be so intense as to flatten or obliterate the normal contour of the affected side. When the blood or urine gains access to the peritoneal cavity the classical signs and symptoms of peritonitis may develop.

Exclusion of other traumatic causes of hematuria, such as injuries to the bladder or urethra, is necessary before the diagnosis of renal damage is reasonably certain.

The treatment of such injuries should be guided by the intensity of the hematuria or signs of internal hemorrhage. Patients with hematuria following an apparently slight injury should be confined to bed for one week after the microscopic signs of blood in the urine have disappeared. Patients with a moderately severe kidney injury are treated usually conservatively but close watch for increasing hemorrhage or infection must be maintained. When the life of a patient is endangered by a severe initial hemorrhage or one which extends over a period of several days, an exploration of the injured kidney is advisable. Again conservatism should be adhered to and as much kidney parenchyma as possible saved. Tamponage suture and partial nephrectomy may be possible in some cases. However, in avulsion injuries or multiple lacerations of the renal substance total nephrectomy is necessary.

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 14, 1930.

Rupture of the urinary bladder occurred in fourteen cases in this series. Rupture of the bladder usually occurs when it is distended; the greater the distention, the greater the vulnerability. An empty bladder, or one containing only a small amount of urine, lies in the true pelvis and receives protection from external violence by its bony walls. Injury to the bladder in this state is usually secondary to fracture of the pelvic bones. The distended bladder projects above the symphysis pubis and is, therefore, exposed to injury from blows to the abdominal wall. This accounts for the greater incidence in chronic alcoholics, prostatics and patients with paralytic bladders.

Rupture of the urinary bladder may be intraperitoneal (12 cases) or extraperitoneal (2 cases). In intraperitoneal rupture the tear is usually present in the posterior median portion of the fundus, whereas in extraperitoneal rupture it is usually anterior.

The symptoms and signs vary according to the site of rupture. Intraperitoneal extravasation results in diffusion of urine throughout the peritoneal cavity and manifests itself as diffuse peritonitis. There may be an urgency but the patient is unable to urinate. Extraperitoneal rupture results in extravasation of urine into the perivesical spaces. A tumor may be palpable in the lower abdomen or pelvis. Later this may become secondarily infected with resultant cellulitis.

Catheterization usually yields only a small amount of bloody urine. When the catheter passes through the tear in the bladder wall large quantities of urine or bloody fluid may return. In one of our patients 7,795 c.c. was obtained in this manner. When this occurs the fluid flows with diminished force and may fluctuate with the respiratory movements.

Other tests include the introduction of a measured amount of water into the bladder, then noting the amount returned. Decrease in the amount returned is evidence of rupture. In small perforations, however, this may not be true. Vaughan and Rudnick in 1924 described a valuable test. During fluoroscopic examination about 400 c.c. of air is injected into the bladder. An intact bladder has a round regular outline. If a rupture is present, no matter how small, air will pass extravesically into the peritoneal cavity or the perivesical tissues. When positive, this test is diagnostic of ruptured bladder. This test was attempted in five cases in this series and was positive in four. In one case the cystogram had a smooth outline and no air was seen to escape into the free peritoneal cavity. At operation a sealed perforation was found in the fundus of the bladder. All cases of ruptured bladder should be operated upon, with repair of the rupture and drainage of the bladder by retention catheter.

Rupture of the spleen occurred in fourteen cases in this series. Subcutaneous rupture of the spleen usually results from direct violence over the splenic area. Indirect violence is uncommon. The damage of the spleen may vary from a subcapsular contusion to partial or complete tears of the splenic parenchyma, or avulsion of the pedicle. Hemorrhage is usually profuse and continuous although it may be stopped temporarily by the formation of a subcapsular hematoma or coagulum. These barriers may later give way and result in a severe secondary hemorrhage. This occurred in one of our cases, an epileptic who was admitted to the neurological service immediately after a convulsion. He was apparently recovering from the effects of his convulsion, when, on the third day following his admission, he suddenly developed symptoms of internal hemorrhage and died. Autopsy revealed a ruptured spleen.

The symptoms of ruptured spleen are those of hemorrhage associated with symptoms of abdominal injury. The initial shock is severe, probably the result of the severe hemorrhage. Pain is usually localized to the left upper quadrant, although some diffuse abdominal pain may be present. Local tenderness and rigidity over the splenic arc are present in the majority of cases. Shifting dullness in the flanks is present with large hemorrhages. The symptoms of secondary or delayed hemorrhage may occur from three to six days after injury.

The treatment of a ruptured spleen is immediate operation. To delay operation is merely to allow the hemorrhage to continue and the patient to become exsanguinated. Blood transfusion is given whenever possible, preferably after the source of bleeding has been removed. It is also of great value pre-operatively in individuals suffering from severe shock and loss of blood. The type of operation depends upon the condition of the patient and the pathology found in the spleen. Tamponage may be used, if the patient is in poor condition. This method carries the danger of secondary hemorrhage and infection. Suture of the spleen may be indicated in small ruptures on the upper surface of the spleen. It is of little value in extensive ruptures, especially if they involve the lower surface of the spleen. Splenectomy is the operation of choice. Removal of the spleen apparently has little effect upon the individual. There may be a slight secondary anemia and a moderate leukocytosis that may last for years. Lee reported a case which showed that the splenic tissue cells that are extravasated with the blood throughout the peritoneal cavity may become implanted on the visceral and parietal peritoneum and develop into nodules, varying in size up to those a half inch in diameter. These nodules undoubtedly take up the function of the spleen and are histologically described as typical splenic tissue.

Rupture of the liver was found in twenty-three cases in this series. Liver injuries were very often complicated by severe injury to other organs or fractures of bones. The liver, by virtue of its position between the ribs and the vertebral column and of its heavy and inelastic parenchyma, is easily ruptured. The violence may be directly over the liver. Indirect violence is less common, although a fall from a height, with the individual landing on his feet, may cause the liver to be torn from its attachments to the diaphragm. The right lobe is injured about six times as frequently as the left, the convex surface twice as often as the concave. The injury may vary from a superficial rupture to complete tears through the entire organ.

The symptoms of ruptured liver in general are those of internal hemorrhage with symptoms of local trauma. Pain and tenderness over the hepatic area may be evident in some cases. Diffuse abdominal pain may likewise be present in some. Pain radiating to the shoulder is not uncommon. Dullness in the right flank may be present, if the hemorrhage is severe.

The treatment of ruptured liver depends upon the amount of hemorrhage that has occurred. The greatest danger of hemorrhage, as shown by Edler, is during the first twenty-four hours following rupture. After this, the hemorrhage generally ceases spontaneously. In the absence of marked rigidity of the abdominal muscles, increasing abdominal pain and the usual symptoms of severe internal hemorrhage, the patient may be treated conservatively. He should be watched for symptoms of secondary hemorrhage or infection. If symptoms of progressive internal hemorrhage appear, there is no choice but to operate. The injury to the liver may be sutured by blunt needles or packed.

Rupture of the liver in one case of this series was associated with rupture of the gallbladder. In one case the gallbladder alone was ruptured.

The symptoms of rupture of the gallbladder or biliary passages are those of a local or diffuse chemical peritonitis. About half of the cases show the development of a cystic swelling in the immediate neighborhood of the liver. Jaundice is uncommon with rupture of the liver, occurring in only 4.75 per cent of the cases. It is, however, very common in injuries to the gallbladder or biliary passages, occurring in about 65 per cent of cases. In the majority of cases jaundice appears within a few days. It may occasionally be delayed for several weeks.

Immediate operation is the treatment of choice. Suture and drainage of the gallbladder or a cholecystectomy may be necessary.

Rupture of the intestines occurred in ten cases. The portions of the intestine most easily ruptured are the upper jejunum and lower ileum. These portions, because of their short mesentery, are more likely to be found in front of the lumbar vertebræ and are most liable to be crushed by blows to the abdominal wall. The duodenojejunal junction may be torn from its attachment to the ligament of Treitz. This, however, is uncommon, occurring in only three cases of a series of 132 cases of ruptured intestine reported by Berry and Guiseppe. The intestines may burst from a blow to the abdominal wall. This must be rare, since it can occur only when the intestines contain an unusually large amount of fluid or gas, or are obstructed. Multiple ruptures of the intestines are not uncommon, and the lesions are usually close together.

The symptoms of rupture of the intestines are variable. The symptoms of shock are frequently absent in the early stages and are often present in abdominal contusions in which the intestine remains uninjured. It is of little value in the early diagnosis of injury to the intestine.

Pain may be continuous and increasing in severity and is a most reliable symptom. It may extend or gradually shift in position. Vomiting is frequent and, if associated with pain, is quite suggestive of a ruptured intestine. Rigidity of the abdominal wall is a very valuable symptom, if it persists for more than a few hours after the accident. Pulse and temperature are not reliable in the early stages, but as peritonitis develops, they tend to rise.

Obliteration of the liver dullness, especially if percussion is made along the right axillary line with the patient lying on his left side, is a very valuable sign. A much more dependable sign is the demonstration of free air in the peritoneal cavity by fluoroscopic examination. Although the presence of free air is pathognomonic of a rupture of an air-containing viscus, its absence does not rule out injury to the intestine.

All cases of abdominal injury in which the symptoms are at first indefinite should be kept under close observation for symptoms of peritonitis. The increase in severity and a shifting of the abdominal pain are of value. The gradual rise in the pulse rate in the absence of the usual symptoms of hemorrhage and a gradual rise in the temperature and leukocyte count are indicative of a spreading peritonitis and demand immediate operation.

Immediate operation is indicated in all early cases of rupture of the intestine. Conservatism may be advised in cases first seen four or five days after the injury. An operation at this time may break up the limiting adhesions that nature has laid down to wall off the perforation, thereby converting a local into a diffuse peritonitis. A later operation for the drainage of an abscess or repair of a fecal fistula is less dangerous.

Some cases of ruptured intestine recover spontaneously, with or without abscess formation. In this series one case was operated upon for an intestinal obstruction six weeks after an injury to the abdomen that was treated conservatively. At operation a walled off perforation was found in the ileum, and there was an intestinal obstruction from the strangulation of a loop of gut that had entered a traumatic vent in the mesentery.

Rupture of the pancreas occurred in three cases of this series. The prevertebral portion of the gland alone may be injured. The rupture may involve only the parenchyma, leaving the duct intact, or it may include the duct with the resultant extravasation of large quantities of pancreatic juice in the lesser, and, at times, the greater peritoneal cavity.

There are no special signs or symptoms of rupture of the pancreas. One must rely upon the steadily increasing severity of the symptoms following upper abdominal injuries. The shock deepens, pain becomes marked and the symptoms of peritonitis are prominent.

Patients with these symptoms are usually subjected to an exploratory laparotomy. During this type of operation it is important not to overlook the pancreas, which may be adequately explored through the gastro-hepatic omentum. Care must be taken not to soil the peritoneal cavity with pancreatic juice. The bleeding may be carefully arrested by ligature en masse, or, preferably, by suture. If the tail of the gland is badly crushed, a resection of this portion may be performed. Drainage may be established through the anterior wound or through a special posterior wound. If the duct has been injured there may be a copious drainage of pancreatic secretions. In one case of this series a fistula formed from which pure pancreatic juice was obtained.

There are milder degrees of pancreatic injury not demanding immediate operation. These may give rise to large pancreatic cysts. One case of this series developed a large pancreatic cyst two weeks after a blow to the upper abdomen.

The mesentery should always be explored during operations for abdominal injuries. Tears of the mesentery may give rise to copious hemorrhages. If these tears are not repaired they may become the site of an internal hernia and, possibly, strangulation of the gut, as in the case cited.

Rupture of the epigastric vessels is not uncommon. A large hematoma may form and this must be differentiated from an intra-abdominal mass. The hemorrhage usually ceases spontaneously and the hematoma absorbs without surgical intervention.

CONCLUSIONS

Non-penetrating injuries of the abdomen may be divided from a surgical standpoint into two groups.

Group 1 includes those patients who suffer severe injury to one or more viscera, along with single or multiple fractures. These patients are in profound shock and usually succumb in a few hours, or, at most, within one to two days. Since the severity and multiplicity of the traumata precludes the possibility of operative intervention, these cases are of no great surgical interest.

Group 2 includes those cases with less extensive injury, such as rupture of one organ, generally unaccompanied by a serious fracture. It is this second group which commands the diagnostic skill and surgical judgment of the attending surgeon, for here it is necessary to determine not only the extent of injury, but also the advisability of operative intervention.

The symptoms and signs of subcutaneous abdominal injuries can be divided into general and specific. The general manifestations include primary shock, abdominal pain, tenderness, and, at times, rigidity. (The specific symptoms depend upon the organ involved and permit identification of the structure damaged.) Unless one knows which organ is traumatized the advisability of operation is often in question. For instance, an injury to the left loin might result in a ruptured spleen or kidney. The former should be treated by operation, but the latter, perhaps in most instances, conservatively. All available data and all diagnostic aids, including the *x*-ray, are frequently necessary to determine pre-operatively the type of injury present. No patient should be subjected to operation until a thorough immediate study has been made. The time required for this study is no longer than the time needed to "set up" an operating room, provided the examiner possesses the requisite knowledge. By "requisite knowledge" is meant familiarity with the symptoms and signs characteristic of injury to the individual structures as outlined in the body of the paper.

In spite of the most painstaking investigation there remains a certain percentage of cases in which the site of damage remains obscure. In these cases it is unwise to wait or resort to diagnostic measures which are time-consuming. Laparotomy is the only safe procedure in doubtful cases when the patient is seen early.

COFFEY-HUMBER TREATMENT FOR CANCER

Recent developments in the Coffey-Humber treatment of cancer emphasize the fact that the history of investigations of new methods for the treatment of cancer is marked by the wreckage of dozens of scientific reputations, by the bodies of patients, and by bitter controversy among scientific men. Such conditions establish again the importance of provision within organized medicine for careful study and judgment of new methods before they are given circulation to the medical profession or to the public. Had the proponents of the Coffey-Humber method seen fit from the first to follow established custom in the introduction of their technic and their results, had they consulted the Council on Pharmacy and Chemistry as to the proper method of introducing a new proprietary, they might have avoided all the acrimony, the criticism, and certainly all the notoriety that has been their lot. (Jour. A. M. A,. November 1, 1930, p. 1349.)

THE VREELANDS QUACKERY AGAIN

Recently the Jour. A. M. A. published an article, "The Vreelands Quackery," regarding a fraudulent grow-hair-quick concern run by one Clayt Vreeland of Cleveland, Ohio. In this article it was brought out that among the testimonials used was one from a physician, Dr. C. J. Cannon. Dr. Cannon believes that the reference to his testimonial did him an injustice because it was used without his consent. The fact remains that he gave the testimonial and further that he should have been aware of its use. In 1928 a layman wrote to Dr. Cannon stating that he had read the data received from Vreeland and saw his letter there. The layman asked for the reasons why he considered the preparation good and Dr. Cannon replied that he considered the people honest and reliable and suggested that he call at their office for examination and advice. (Jour. A. M. A., August 23, 1930, p. 613.)

HEPATIC ABSCESS FOLLOWING ACUTE APPENDICITIS WITH RECOVERY*

REPORT OF CASE

Ernest R. Anderson, M.D., and R. C. Webb, M.D.
Minneapolis

ABSCESS of the liver is one of the most dreaded complications of appendicitis. According to Loison,[30] Waller, in 1846, described the earliest case that is recorded in the literature. Other early cases are reported; one by Hillariet[24] in 1849 and one, in 1854, by Buhl,[24] who described a case of multiple abscess of the liver following appendicitis. The cases reported in the early literature were of autopsy findings. The condition was considered as a rare occurrence and invariably fatal. Dieulafoy[8] in 1898 considered that hepatic abscess secondary to appendicitis was always fatal. Deaver[13] in 1921 states that they have never seen a case of liver abscess following appendicitis recover.

When Loison[31] reported to the Societié de Chirurgie de Paris in 1900 a case of hepatic abscess following appendicitis that recovered, Poirier and Tuffier questioned the diagnosis. The earliest case of hepatic abscess, secondary to appendicitis which recovered after surgery, is the one reported by Körte[31] in 1892. In the more recent surgical literature there have been recorded cases of recovery from hepatic abscess following appendicitis.

The following is a case record of a liver abscess complicating acute appendicitis with recovery.

CASE REPORT

R. W., a male, aged 15, was admitted to the Abbott Hospital, Minneapolis, September fourteenth. The patient had always been in good health prior to September 12, 1929, when at 2 a. m. he began to have abdominal cramps which were generalized and persistent, not associated with nausea or vomiting. The following day he went to school. On September 13th he remained at home and took only a liquid diet. The next day he was still ill and was given a cathartic. At 2 p. m. on that same day, September 14th, he began to have pain localized in the lower right quadrant of the abdomen. Dr. E. J. Huenekens saw him at 6 p. m. and made the diagnosis of acute appendicitis with peritonitis. He arrived at the hospital at 7:10 p. m. having a temperature 100.2 degrees, pulse 112 and respiration 22. At 8 p. m. appendectomy was performed. A ruptured gangrenous appendix was removed and an inversion of the appendical stump was done. A generalized peritonitis with turbid fluid in the peritoneal cavity was present. A tubular rubber dam drain was placed into the pelvis and one was passed in the lateral gutter between the ascending colon and the parietal wall. A Gibson[43] rubber dam tampon drain was inserted in the McBurney incision and no closure with sutures was done.

The postoperative period was stormy. On the third day the temperature rose to 103.8 degrees and then gradually receded so that it was between 98.4 and 100.6 degrees until the twelfth postoperative day. From that day on the temperature curve was of the septic type ranging from 98.4 to 104.4 degrees. There were no chills accompanying the elevation of the temperature. The patient had spells of profuse perspiration.

From the first postoperative day there was abdominal distention and some emesis until the seventh day postoperatively. Beginning September 20th the patient complained daily of shooting pains in the lower left chest anteriorly and on September 25th began to have pain in the lower part of the right chest anteriorly. On deep breathing pain was produced. The pain persisted and on October 2nd tenderness developed below the right costal margin. The liver was enlarged and a bulging of the abdominal wall, which was tender, was noted in the right upper abdominal quadrant.

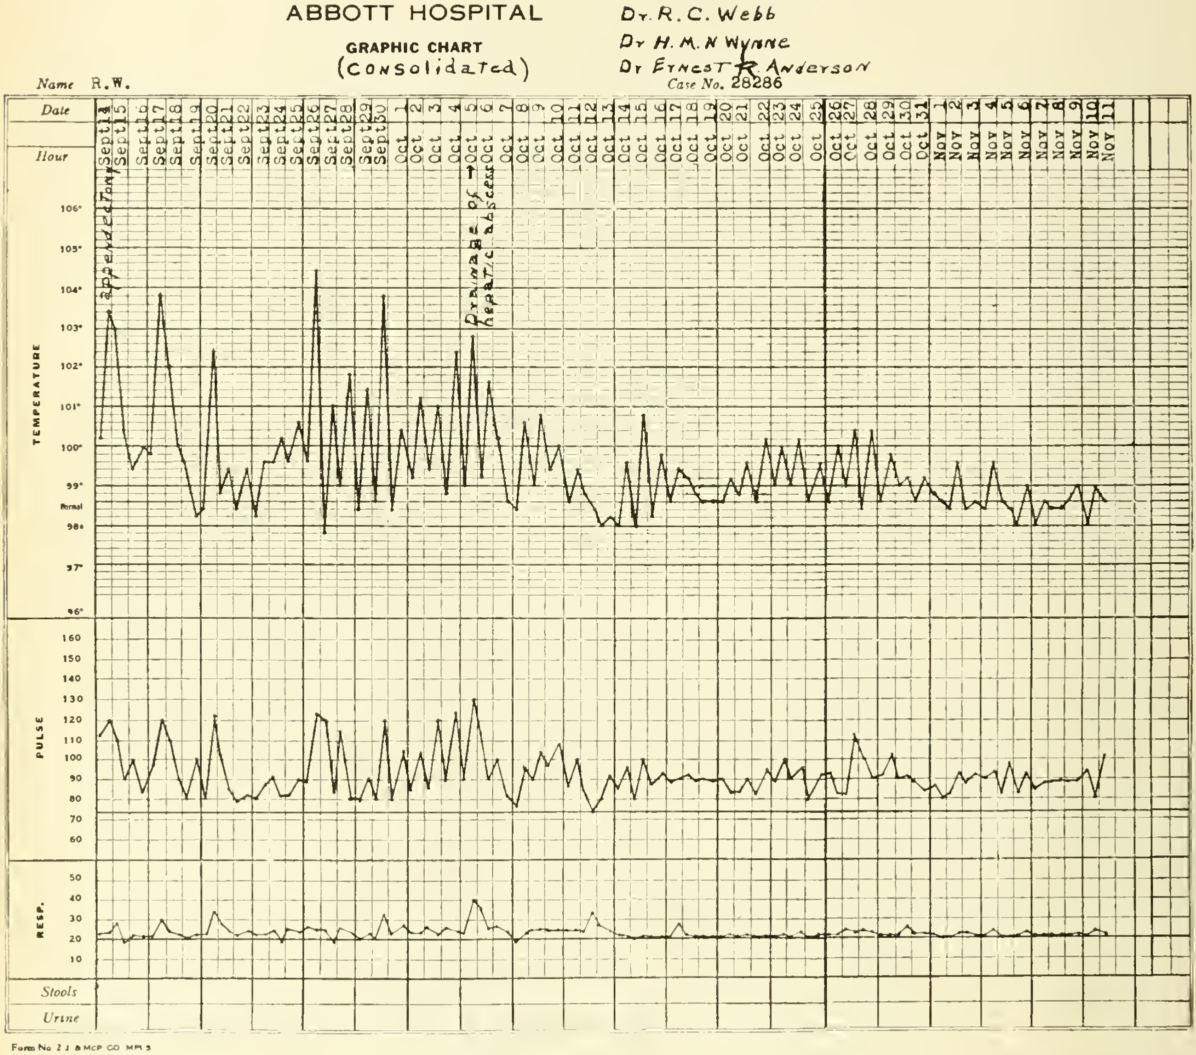
The patient at times presented a picture of being drowsy, listless, and extremely ill; and then again there were intervals when he was alert and bright. There was no jaundice of the sclera or skin present.

Clinical and *x*-ray examinations showed the lungs normal. On September 25th the leukocyte count was 27,000, the differential count: polymorphonuclears 81 per cent, small lymphocytes 14 per cent, large mononuclears 4.5 per cent, and eosinophiles 0.5 per cent. On October 3rd the leukocyte count was 26,000, the differential count being: polymorphonuclears 79.5 per cent, small lymphocytes 15 per cent, large mononuclears 5 per cent, and basophiles 0.5 per cent. The urinalysis on September 25 was: Sp. Gr. 1.012, amber color, clear, alkaline reaction, very faint trace albumin, no sugar, and 1 to 2 pus cells were present. The test for biliary pigments was not performed.

On October 5, under nitrous oxide and oxygen anesthesia, a laparotomy was performed, making an exposure of the liver through an upper right rectus incision. The inferior edge of the liver was fastened to the anterior parietal peritoneum 3.5 inches below the costal margin. The adhesions were not disturbed. On the anterior surface of the right lobe of the liver there was a soft bulging two inches in diameter. The overlying liver tissue was speckled with yellowish pinhead-sized spots.

---

*Read before the Minneapolis Surgical Society, October 2, 1930.



An aspirating needle was inserted and pus obtained from a depth of one inch. The opening into the abscess was made by inserting a clamp along the needle and by spreading the points of the forceps. The abscess cavity was irregular and slightly larger than an English walnut. A gauze pack was placed in the abscess cavity. A direct smear of the aspirated material showed many pus cells. Culturing the same material produced an abundant growth of B. coli.

The temperature gradually became lower and from November 5th it remained normal. The second incision was healed October 19th. The patient was discharged from the hospital November 11th. Since then he has gradually gained in weight and now is a normal boy for his age.

INCIDENCE

The occurrence of hepatic abscess following appendicitis varies but slightly in the recent series that have been reported. Eliason[13] states that in 2,237 cases of acute appendicitis operated at the University of Pennsylvania Hospital three cases of liver abscess developed, making an incidence of 0.13 per cent. In a series of 1,650 cases of appendicitis, Lindquist[29] had four cases (0.24 per cent) of hepatic abscess. He states that Petren found abscess of the liver developing in 0.3-0.4 per cent of the cases of appendicitis. Krogius, as quoted by Babler,[2] observed two cases (0.2 per cent) of liver abscess in 1,000 cases of appendicitis. In 2,714 cases Rendle Short[3] found suppurative phlebitis occurring 0.4 per cent. Two cases (0.11 per cent) of hepatic abscess were observed by Stillman[8] in a series of 1,748 cases of appendicitis.

In the early literature the incidence reported is higher. Gerster[21] in 1,189 cases observed nine (0.7 per cent) of hepatic abscess. Munro[33] estimated the occurrence of hepatic abscess to be 5 to 10 per cent in all cases of appendicitis. In 257 cases Fitz[19] found eleven (4.2 per cent). Five per cent of 546 post mortem examinations of patients dying of appendicitis were found by Armstrong[11] to have had liver abscess and pylephlebitis.

MORTALITY

It has been taught that the mortality in hepatic abscess following appendicitis is very high. This is stated in the text books on the subject and the experience of the early surgeons and pathologists seems to corroborate this fact. In the series which have been reported more recently we obtain encouragement. Petren[29] reports twenty-two cases which were operated upon that ended in recovery. Eliason[16] in 1926 collected from the literature fifty-three cases with a mortality of 59 per cent and to this he added fourteen cases, seven of which resulted in recovery. That reduced the mortality to 54 per cent. Since then, cures have been reported by De Planque,[14] Reök,[38] Barnes and Pearson,[4] George[20] and Lindquist,[29]—one case by each author. During that same time hepatic abscesses following appendicitis, which were operated upon and ended fatally, were recorded by Reök,[38] Martini and Staemmler,[32] Navarro,[35] and Nieweg,[37] each having had one case, and Lindquist[29] three.

Including the case reported in this paper, there are six recoveries in a total of thirteen cases which have been reported in the literature since Eliason's[16] series. The mortality in these thirteen cases is 54 per cent, which is the figure that occurred in the collected cases of Eliason. With the chance of helping about one-half of these hepatic abscesses following appendicitis, surgical intervention is justified. Formerly when no surgical procedure was instituted, these patients died.

MODE OF INFECTION

The routes by which the infection travels to the liver from the appendical region, are readily understood when the anatomy is kept in mind. The most common route is for the infection to be carried along the portal system. From the veins which drain the infected appendical region, bacteria or infected emboli get into the portal circulation, traveling by way of the ileocecal, ileocolic, and superior mesenteric veins into the portal vein and then into the liver. The infected material can travel through these veins without establishing an inflammatory process and be lodged in the liver to be the nidus for the development of an hepatic abscess. This mode of infection is apparently the route the infection traveled in the case herein reported.

With appendicitis there is associated a lymphangitis and lymphadenitis. The regional lymph drainage from the appendix is into the retroperitoneal tissue and toward the diaphragm. The septic material from the appendix can produce a retroperitoneal inflammatory process with abscess formation and from such a focus hepatic abscess can form. Lindquist[29] reports a case where this mode of infection was the possible route.

If a general septicemia follows an appendicitis it is possible for an hepatic abscess to originate from infectious material entering through the hepatic artery. This means that the infection arising from the appendix may have passed through the liver and then entered the general circulation to establish the septicemia. The prognosis in these cases is very grave, as the generalized septicemia is more than the organism can withstand. Several abscesses scattered throughout the body may be produced, the hepatic abscess being only a local manifestation in the liver of what is occurring throughout the system.

Hepatic abscess can be produced by contiguous abscesses that occur following appendicitis. Subhepatic abscess or a subphrenic abscess that has formed from an appendicitis can extend into the liver and involve the parenchyma of that organ. A breaking down of the tissue with the formation of an abscess in the liver results. These cases do not often occur. However, the reverse of this situation happens: an hepatic abscess is formed and found situated near the surface of the liver; it breaks through the capsule, forming an abscess subphrenically or an abscess at whatever point it ruptures.

Infection from an appendicitis which has produced an inflammatory condition of the biliary system, as is manifested in some cases by the occurrence of jaundice, can be the source of the formation of hepatic abscess. The abscesses and inflammatory process have been found to be distributed in the liver along the biliary system. The occurrence of this mode of infection is thought to be rare.

PATHOLOGY

The number of abscesses which have been found occurring in the liver following appendicitis varies. There may be a single abscess or the liver may be riddled with a great number. The condition produced depends upon the amount of infectious material entering the liver. A single embolus may originate from the periappendical region and be carried to the liver to produce a solitary abscess. A single hepatic abscess may occur by the coalescence of several abscesses situated in close relation to one another.

Where there is an abundance of bacteria carried to the liver from the appendical region or from a pylethrombophlebitis several abscesses are formed. A large amount of liver tissue can be destroyed by the formation of multiple abscesses and a severe degree of cholemia be produced. That, with the overwhelming infection, usually proves fatal.

Hepatic abscesses that have occurred have been of different sizes. Some were very small, being only minute spots in the liver; others were larger, approaching the size of amebic abscesses which are seen in the liver. Usually these secondary abscesses do not attain a large size. Some, however, are the size of an orange. The single abscesses are the ones that become the largest.

The distribution of hepatic abscesses is not limited to any certain portion of the liver but may occur in any lobe. The greatest number of abscesses have been found in the right lobe. The abscesses occur in the right lobe five times more often than in the left.[1] Sérège[8] thought that there were two currents of blood in the portal vein. He concluded that the flow from the superior mesenteric vein went to the right lobe and the blood from the inferior mesenteric and splenic veins flowed into the left lobe. He made his conclusions from a study of India ink injections. From the experimental work of Dominici[15] one can not admit that there are two streams of blood in the portal vein.

As there is a greater volume of liver parenchyma in the right lobe and as the branch of the portal vein to the right lobe is of a larger caliber, it would seem that the chance of infectious material getting to the right lobe would be greater than to other portions of the liver. Because of the anatomical relationship it is easier for infectious material, no matter from what vein it originally comes, to enter the right branch of the portal vein.

The abscesses may occur in any part of the liver. The parenchyma can be interspersed with multiple abscesses as seen in cases of appendicitis where there has been a great deal of infectious material carried to the liver. A single hepatic abscess can form deep in the liver parenchmya or near the surface. Many times they are formed on the dome of the liver. Located in this region they may give findings that might be interpreted as a pathologic process occurring in the base of the lung. When the abscess is situated on the anterior surface of the liver there may be signs of an upper abdominal disease, as a ruptured duodenal or gastric ulcer, or gallbladder disease.

Bacteriologic studies have revealed the same organisms in liver abscesses as have been recovered from infected appendices. This list includes practically the entire group of pyogenic bacteria. On culture, bacillus coli was found to be present in the hepatic abscess of the case herein reported. In Eliason's[16] group of cases, eight were cultured. In four, streptococcus; in three, staphylococcus; and in one, bacillus coli were found.

SYMPTOMS AND SIGNS

The symptoms which occur in hepatic abscess are not at all constant. Because of the variance of the symptoms, the diagnosis of hepatic abscess is in many cases not made until the condition has been present for some time. The development of symptoms can be continuous with the onset of the appendicitis, as hepatic abscess has been known to have its origin in the first few hours of appendical disease. Hepatic abscess may in other cases occur several days or months after the primary attack of appendicitis. The appendicitis may be an acute rapidly progressing condition or hepatic abscesses have been known to follow cases where the appendix was only mildly infected and in some cases, as recently reported by Nieweg,[37] the original appendical process was entirely obscured and unrecognized. The recognition of a previously existing appendicitis may in some of the cases be of help in finally determining the existence of an hepatic abscess.

When an hepatic abscess secondary to appendicitis exists, the elevation of the temperature is a constant sign. The septic type of fever is in response to the infectious process. The fever may or may not be associated with chills. Gerster[21] states, "Chills accompanied by a rapid rise of temperature observed during the course of appendicitis, however mild as to the local symptoms, may and usually does signify the entrance of septic material into the portal and general circulation." There may be repeated chills with an increase in the temperature or in other cases only chilly sensations may be present.

Pain is often present but is not a constant symptom. The pain may be located in several places. It may be noticed in the right upper quadrant of the abdomen. Sometimes it is localized below the right costal margin and one may have it occur over the lower ribs of the right side. Some have had pains in the back and others have had referred pains in the right shoulder.

The character of the pain varies; some patients complain of a dull constant aching type of pain; others experience sharp intermittent pain. Where the abscess is located near the diaphragmatic surface, pleuritic type of pain occurs. Abscesses that are placed deep in the liver parenchyma frequently do not produce any pain. The location of the pain may indicate the place where the abscess has developed in the liver.

When carefully looked for, tenderness of the liver is present a greater number of times than the complaint of pain. The elicitation of tenderness in some cases is made by very light pressure over the liver while in others Murphy percussion is required to verify the finding. In the case reported at this time the tenderness was marked; the pressure of the bed covers produced pain in the region over the liver.

In a large number of hepatic abscesses that occur following appendicitis, jaundice is a prominent symptom. The jaundice is intense in some cases and in others very mild, being detected only in the sclera. The occurrence of excessive bile pigment in the circulating blood can not always be detected clinically but the laboratory will show its presence.

The jaundice may appear early in the course of the disease. Soon after the onset of the appendicitis the icterus may appear and it may be thought that an obstructive biliary condition exists. The early appearance of jaundice is an evidence that the liver is being called upon to take care of toxic material coming to it through the portal circulation. In cases of appendicitis that are not complicated by hepatic abscess, jaundice has been known to occur soon after the onset of the disease.

When an abscess in the liver has formed, jaundice may occur. The destruction of the liver parenchyma may be so great that a cholemia results and the icterus becomes an established finding. With an hepatic abscess present there are cases where the jaundice does not occur nor is urobilin found. Eliason[16] states that jaundice is invariably present.

In some cases gastric disturbance may be a prominent symptom. There is a persistent and unrelieved nausea associated with emesis. Liquids or food are not retained and the maintenance of the individual's nutrition becomes a grave concern. Gastric disturbance can be entirely absent. This symptom is inconstant and does not aid materially in arriving at a diagnosis.

With an intraphepatic process an increased volume of the liver is found. The amount of the increase varies. In some cases the enlargement is found only at autopsy while in others the increased size of the liver is easily detected clinically. The enlargement that occurs is uniform and the liver margin can be detected extending below the costal margin. Care should be exercised in determining the height of the superior hepatic margin, as one may interpret the finding of a low lying liver as being an enlarged liver, where the locating of the superior margin would give evidence of a normal liver volume.

In case there exists an abscess on the anterior surface or near the inferior margin, the liver may present clinically an irregularity on its surface. This is rare, as the majority of livers will present a uniform enlargement and the surface will be smooth. The enlargement is due to the swelling of the liver parenchyma in response to the presence of the inflammatory process.

The edema of the tissue overlying the liver was a finding that was noted in the cases observed by Eliason.[16] A thickening of the abdominal wall in the right upper quadrant and on the side of the abdomen which had the characteristics of a lymph edema was noted. The detection of the edema can be made by picking up the tissue of both flanks. By comparison the side involved will be found to be thicker. In the fourteen cases observed by this writer, edema was found in eleven cases. This finding was not present in the case which is being reported.

It has been noted that with hepatic abscess there is a marked degree of general malaise. In the beginning of the illness, the malaise present is usually of such degree as is seen with a far advanced and severe pathological process. The physical findings in these cases are negative or very meager and out of proportion to the weakness which the individual has. The diagnosis will be doubtful until other findings develop as the condition progresses.

The leukocyte count will invariably be elevated in these cases. An increase in the percentage of polymorphonuclear cells occurs. The leukocytosis varies from a slight increase to a count near 30,000. With the drainage of the abscess the leukocytosis diminishes. These findings in the blood are the same as are found in any case of an infectious process.

In the urine, bile and bile pigments may be present. In one series reported, only one-third of the cases had urobilin present in the urine. As a diagnostic aid, the finding of bile pigment in the urine shows a disturbance of liver function and, with the other clinical findings, helps to arrive at the diagnosis of hepatic abscess.

The *x*-ray will in many cases give evidence of hepatic abscess. A raised diaphragm on the right side, which is found on fluoroscopic examination to be stationary, speaks for hepatic disease. A subphrenic collection of pus gives an altered diaphragmatic shadow and, to differentiate it from an abscess in the liver, paracentesis will have to be resorted to in many cases.

Roentgenograms have revealed changes in the base of the right lung and in the right pleural cavity in cases of liver abscess. There has been a thickening of the parenchyma in the base of the right lung and in some cases fluid has collected in the right pleural cavity. These findings have been interpreted as being of pneumonic origin and the hepatic process which existed was obscured. Christopher[9] has recorded a case in which liver abscesses and pylephlebitis secondary to a gangrenous appendix simulated lung abscess. Some of the cases of Eliason's[16] series were diagnosed basal pneumonia.

With the diagnosis of hepatic abscess secondary to appendicitis difficult, on account of the varied symptomatology, one wonders how many of the pneumonias, diagnosed following inflammation of the appendix, are pneumonias. The edema of the tissue around the liver in cases of hepatic abscess can produce lung changes and exudation into the pleural cavity which will give clinical findings simulating pneumonia. In such type of cases the diagnosis may be very difficult and tax the skilled surgeon. The occurrence of basal pneumonia following appendicitis should be regarded as a possible hepatic disease and be determined if necessary by aspiration.

When the aspirating needle is used it should only be for the localization of the abscesses. With pyogenic abscesses the danger of spreading the infection to the pleura or to the peritoneum is great, so preparation should be made, if an abscess cavity is entered, for incision and drainage. The place of the puncture is chosen over the area of greatest swelling or edema of the abdominal wall or over the place of the most tenderness. If the *x*-ray shows an elevated diaphragm, exploratory puncture is made under the diaphragm.

TREATMENT

The treatment of hepatic abscess following appendicitis can be considered as of a prophylactic nature and that which is concerned with the management of the established abscess. With the early diagnosis of all cases of appendicitis and the early removal of such appendices the incidence of hepatic abscess will be lowered. The infectious foci will be removed and will not be the sites from which bacteria or infected thrombi can originate and enter the portal circulation. The reduction in the occurrence of hepatic abscesses which has taken place in the last thirty years is in a great part due to the early recognition of appendicitis and immediate operation.

If at the time of the appendectomy the veins in the mesoappendix and periappendical veins are found thrombosed, there are some surgical procedures that can be done, which are calculated to reduce the possible development of hepatic abscess and pylephlebitis. These procedures constitute: the removal of the thrombi, the incision and drainage of the thrombosed veins, the ligation and incision of the veins involved, the ligation of the ileocolic vein, or the ligation of the portal vein. Several surgeons have reported cases where some prophylactic measure has been done. Gerster[21] practised the incision and drainage of the infected thrombosed veins that were found; Wilms[11] advised the removal of the veins in the ileocecal angle; Braun[11] performed the ligation of the ileocolic vein. Each has reported cases of recovery. In far advanced cases of thrombophlebitis and pylephlebitis Colp[11] described the ligation of the portal vein in three cases with no recoveries. In regard to the prophylactic measures Thalhimer[41] states, "Every case of acute appendicitis should be considered as an early case of potential pylephlebitis whether there is a history of chills or not. Consequently, the appendix and its neighborhood should always be carefully inspected for the presence of small thrombosed veins so that these can be dealt with."

The management of hepatic abscess following appendicitis is like that of any pyogenic abscess that occurs in the liver from any cause. The object of the surgical measures is to establish drainage of the abscess. The approach of any hepatic abscess is determined by the findings and symptoms of each individual case. The location of the abscess may be such that the method of choice is by making an incision in the right upper quadrant of the abdomen to expose the liver and drain the abscess. This approach was used in the case reported at this time.

Where the abscess is located on the anterior surface of the liver or on the convex surface, the approach will be different. A two stage transpleuro-diaphragmatic operation is utilized in approaching and draining the abscesses in the dome of the liver. Where the abscess is located on the anterior surface a rib resection can be done and a transdiaphragmatic approach below the reflection of the parietal pleura be instituted. In some cases where the abscess is situated on the posterior surface of the liver a similar procedure can be carried out from the back.

As the development of the hepatic abscess may remain obscured for a long time, the general condition of the patient will need supportive treatment. The sepsis can be combated by using blood transfusions and by intravenous injections of glucose solution. These measures are sometimes necessary after the drainage of the hepatic abscess in cases where the individual is greatly weakened.

COMMENT

The occurrence of hepatic abscess following appendicitis does not necessarily mean a fatal condition. With the recognition of the liver abscess and the early establishment of drainage, there is about a 50 per cent chance of recovery. It is needless to say that with the opportunity of saving at least half, these liver abscesses should have the benefit of surgery. The factors which will perhaps improve the present mortality rate are: (1) early diagnosis of appendicitis and early operation; (2) the recognition that the latent and recurring cases of appendicitis are sources of hepatic abscesses; (3) the carrying out of prophylactic measures in indicated cases; and (4) the early diagnosis of hepatic abscess and the early establishment of drainage.

VAGINAL HERNIA*

REPORT OF TWO CASES OPERATED

E. K. Green, M.D., and L. K. Buzzelle, M.D.
Minneapolis

THE term hernia is applied to a defect which allows the escape of structures normally held within a cavity. There seems to be a great deal of confusion as to just what constitutes a vaginal hernia. The pelvic floor, which normally acts as a barrier to the abdominal contents and serves to hold the pelvic organs in position, is subject to all sorts of injuries and malformations. The repair of these abnormal conditions constitutes a large proportion of gynecological surgery.

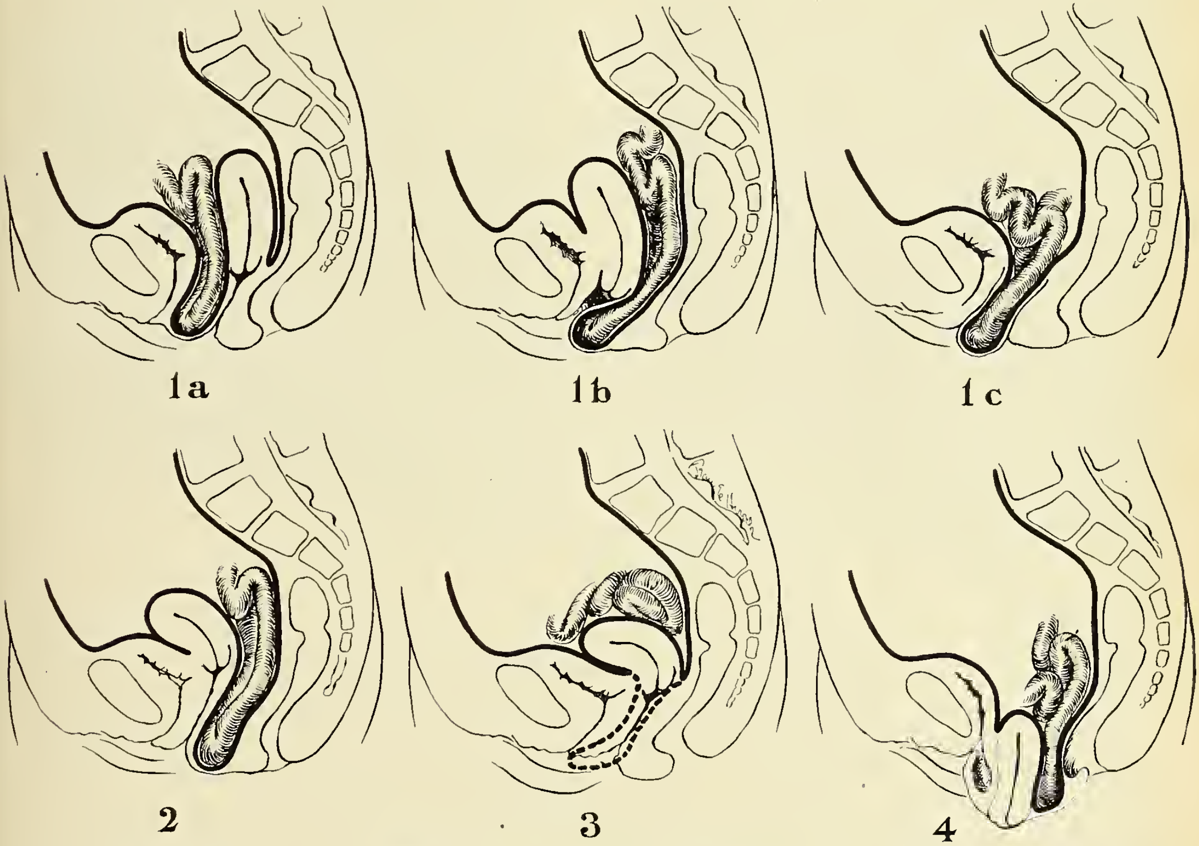

Fig. 1. Diagram showing our classification.

Dr. L. M. Miles of Peking, China, published an article in 1926 in Surgery, Gynecology and Obstetrics in which he reviewed the literature, picked out nine cases which he considered typical, summarized them and reported two of his own. The subject of his article was Pelvic Hernia.

In July, 1928, Dr. J. C. Masson of Rochester in the same magazine reported five cases of a similar nature operated upon at Rochester. The subject of his article was Vaginal Hernia. Obviously the distinguishing point in the minds of both of these authors is that the protrusion which presents itself at the vulva contains abdominal contents such as ascitic fluid or intestines.

Some authors speak of all herniæ in the region of the pelvis as pelvic herniæ and subdivide them according to location or point of egress, while others describe each class separately. We suggest the following classification, which is very similar to that of Dr. Fordyce Barker in his article of 1876.

---

*Presented before the annual meeting of the Minnesota State Medical Association, Duluth, July 15, 1930.

Our classification is as follows:

1. True Vaginal
    a. Anterior
    b. Posterior
    c. Post-operative
2. Perineal
3. Pudendal
4. Complete Pelvic

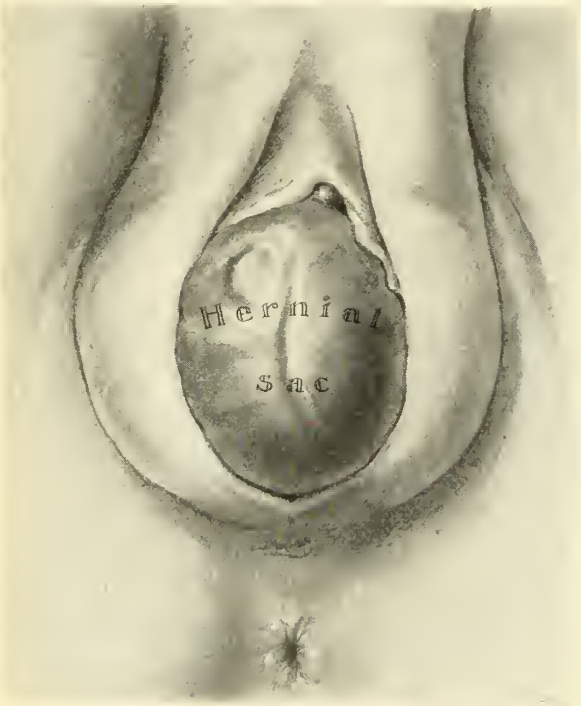

Fig. 2. Case 1. Actual photograph taken on the operating table before operation.

The anterior vaginal hernia dissects its way between the uterus and the bladder, not necessarily producing a cystocele, and appears in the vaginal opening.

The posterior vaginal passes posterior to the uterus and involves the vault of the vagina and recto-vaginal pouch.

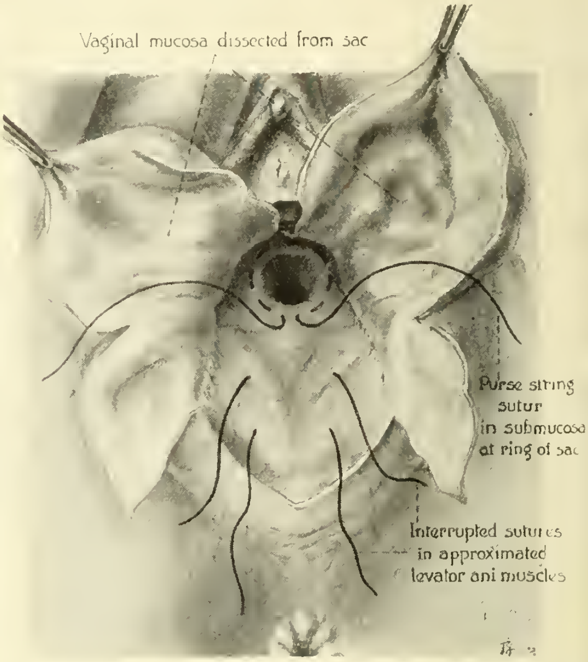
The post-operative hernia follows a hysterectomy and passes through the operative scar in the vault of the vagina.

The perineal hernia passes down through the recto-vaginal pouch, leaving the vault of the vagina practically normal, and pushes the vagina forward, appearing in the perineum, usually a little to one side or the other of the median line.

The pudendal hernia dissects its way down through the side of the pelvis and appears in the labia majora.

The complete pelvic hernia involves all the structures of the pelvis. Besides containing intestines or abdominal contents, we find the bladder, uterus, rectum and vagina involved with much distortion and displacement.

Our two cases according to this classification fall into the true vaginal type, one posterior and the other post-operative.



Vaginal mucosa dissected from sac
Purse string sutur in submucosa at ring of sac
Interrupted sutures in approximated levator ani muscles

Fig. 3. Case 1. Flaps dissected up and the hernial sac pushed up into the abdominal cavity

CASE REPORTS

Case 1.—Mrs. G., fifty-two years of age, has had five labors. She was thirty-two at the time of her first labor, which was very difficult, and she was delivered with forceps by Dr. Green.

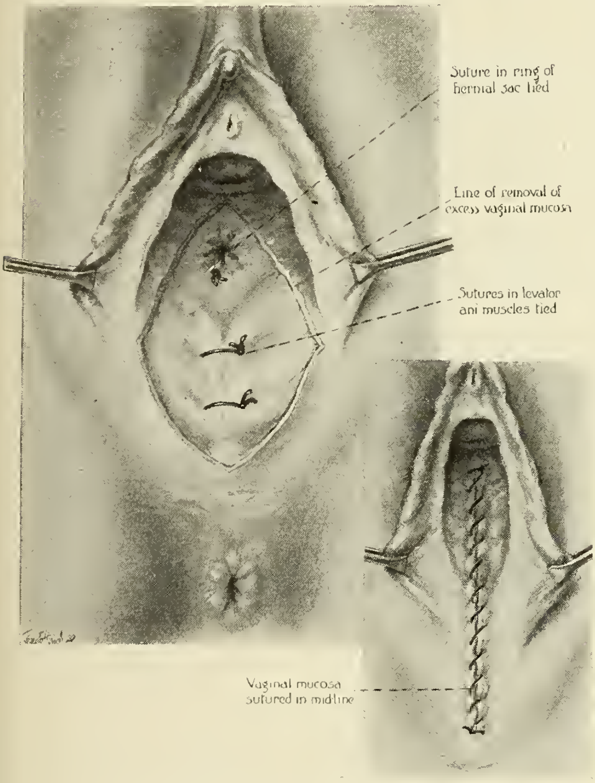
She first came to our office with the present complaint in June, 1928, desiring a support. Operation was advised but she refused.

She came back again January 15, 1929. Examination revealed a mass protruding from the vulva about four inches in width with two deep ulcerations. This mass contained intestines and was easily pushed through the vagina up into the abdominal cavity. The uterus was in good position, there was no appreciable cystocele and no definite rectocele, though the rectal wall was somewhat lax. She was first operated upon per vagina. The peritoneal sac was freed and pushed up into the abdominal cavity and packed with gauze. The redundant vaginal wall was removed and a high perineal repair was made, bringing the levators together after closing the sac with chronic purse-string sutures.

The abdomen was then opened, the gauze removed from the inverted sac, and the sac sewed to the posterior wall of the uterus. The culdesac was then closed after the manner of Moskowitz, suturing the bowel and uterus together in such a way as to obliterate the recto-vaginal pouch.

Examination several weeks later showed no signs of recurrence.

Case 2.—Mrs. P., sixty-two years of age, had had five children. The first at twenty-two years of age, was delivered by a midwife with forceps. At forty-nine she was operated upon by the late Dr. J. Warren Little for complete uterine prolapse. A vaginal hysterectomy and perineal repair was done.



Suture in ring of hernial sac tied
Line of removal of excess vaginal mucosa
Sutures in levator ani muscles tied
Vaginal mucosa sutured in midline

Fig. 4. Case 1. Final perineal repair.

She came to our office January 10, 1929, with a mass about the size of a small orange protruding through the vaginal scar and presenting at the vulva. The hernia, which occupied the whole vagina, contained intestines and could be easily reduced into the abdominal cavity. There was no cystocele or rectocele.

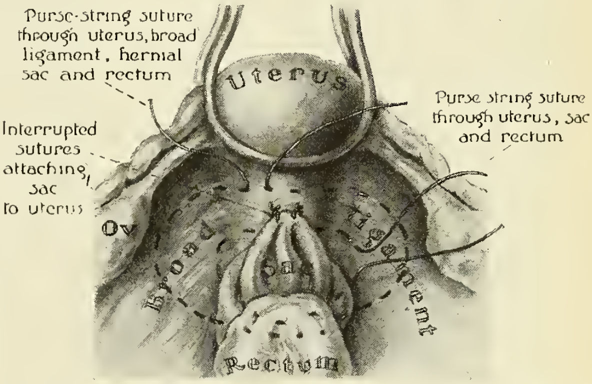
Our operative procedure was as follows: The hernia was reduced and held in the abdomen by a piece of gauze on a forceps while the abdominal operation was begun. After freeing the peritoneum from the hernia, the vaginal portion was pushed down into the vagina, packed with gauze and left while the opening in the sac was closed by chromic purse-string sutures. The broad ligaments were brought together and sutured to reinforce the outlet. We then did the vaginal operation. The redundant tissues were removed and a high perineal repair was done.

Examination some weeks later showed some laxness of the posterior vaginal wall but no recurrence of the hernia.

LITERATURE

In going over the literature it is interesting to note how the various authors who have written on this subject classify their cases.

Dr. Fordyce Barker as early as June, 1876, wrote an article in *The American Journal of Obstetrics,* already referred to in this paper, on the subject of Vaginal Hernia, in which he reported four cases of his own, all complicating delivery. He also mentioned nine other cases in the article and reported one as far back as 1710 by Garengeot. These cases, however, are not sufficiently described to render them fit for classification.



Purse-string suture through uterus, broad ligament, hernial sac and rectum
Uterus
Purse string suture through uterus, sac and rectum
Interrupted sutures attaching sac to uterus
Ov
Broad
Sac
ligament
Rectum

Fig. 5, Case 1. Method of Moschowitz in fastening the bowel to the posterior wall of the uterus.

Nine years later, Dr. T. Gaillard Thomas wrote quite an extensive article in the *New York Medical Journal* on the subject of Vulvar and Vaginal Enterocele. He gave us the first report of a vaginal hernia properly diagnosed and successfully operated upon. The case was one of the posterior vaginal type of an enormous size reaching half way down the thigh. The operation consisted of reducing the hernia and sewing the sac into the abdominal wound. In his article he reported about twenty other cases. We would like to comment on three of these in which there was a mistaken preoperative diagnosis.

In one, the doctor thinking the hernia was an abscess, opened it and found strangulated intestines. The patient died. In another, a tumor complicating delivery was thought to be a cyst, but in attempting to empty it with a trocar, feces were obtained. In the third, there was a sloughing mass in the vagina that was thought to be a uterine polyp. It was removed and a postmortem examination revealed that a portion of the transverse colon and omentum had been removed. Most of his cases were difficult to classify, as was the case in Dr. Barker's article.

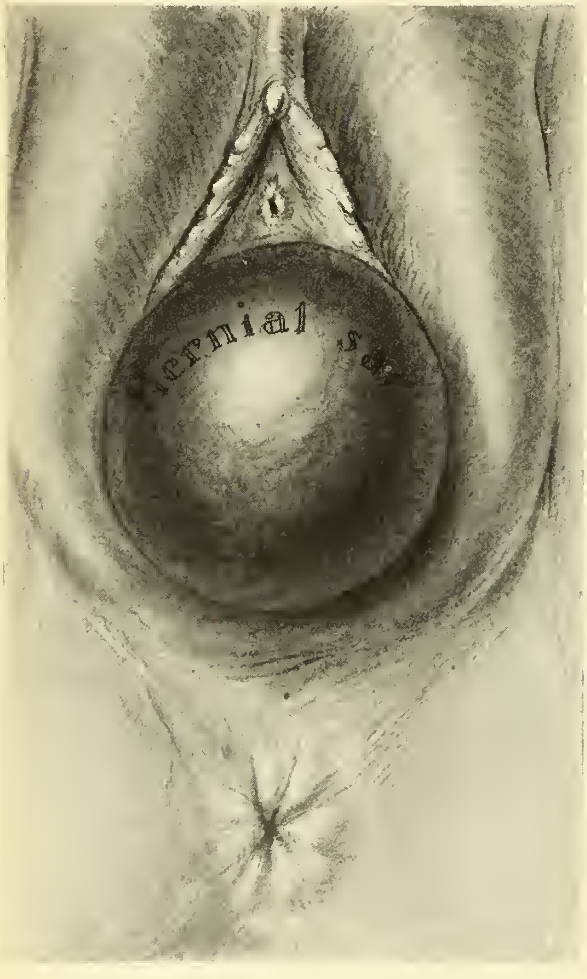


Fig. 6. Case 2. Actual photograph taken on the operating table before operation.

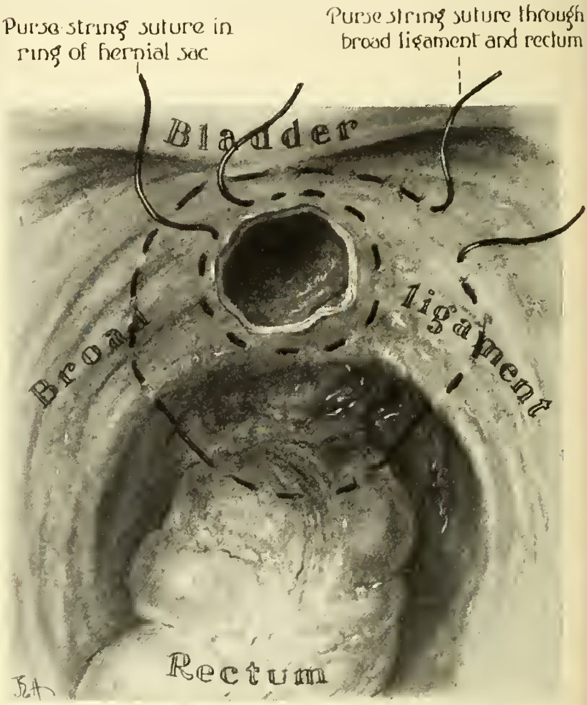
The borderline case is one that is always difficult to dispose of. For example, Dr. George Gray Ward in a very good article in the August, 1922, *Journal of American Medical Association,* on the subject of Technic in Repair of Enterocele or Vaginal Hernia, reported fourteen cases operated upon, three of which had to be reoperated because of mistaken diagnoses. He described these cases as having a particularly low recto-vaginal pouch.

According to our classification we hardly know whether they would be considered posterior vaginal, perineal, or a combination of both, or neither, as some authors suggest.

Dr. Herbert C. Chase, on the other hand, in the December, 1922, *Surgery, Gynecology and Obstetrics,* wrote an article on Levator Hernia (or Pudendal Hernia), in which he reported thirteen cases. Five were operated upon with three failures and two cures. In his article he does not consider them as vaginal hernias at all, yet he speaks of some as obstructing the vaginal outlet and others as pressing the vagina over throughout its entire length.



Purse string suture in ring of hernial sac
Purse string suture through broad ligament and rectum
Bladder
Broad ligament
Rectum

Fig. 7. Case 2. The abdominal method of closing the hernial sac.

In reviewing the literature and trying to classify the cases we are led to believe that, out of fifty or sixty cases reported, probably a comparatively few, perhaps ten or twelve, would be of the true vaginal type, with about an equal number of the perineal type. Among the rest there would be a few of the complete pelvic type, while the remainder would be borderline cases.

The complete pelvic hernia deserves special mention here because it seems altogether probable that if all cases of complete prolapse were carefully investigated, the intestines would be found to be involved in a certain number.

ETIOLOGY

The great majority of cases reported occurred in multipara, but a sufficient number of nullipara were reported (notably Dr. H. B. Sweetser's case) to lead us to believe that a large percentage, if not all of the cases, have a congenital defect which gives way either gradually or at the time of an accident. There is no question, however, that labor is the largest contributory factor. There are three cases reported by Dr. Thomas where an opening was made through the vault of the vagina by external force which allowed intestines to escape into the vagina. One was in a woman who, in attempting to produce an abortion, tore a hole with a douche point. The other two were produced by reputable physicians, one in forcibly examining a patient, and the other in trying to replace a retroverted uterus with gauze on a sponge holder. Strange to say, all these patients recovered. We are inclined to agree with some authors who seem to think these cases are not hernias at all, but we consider them of sufficient interest to mention.

SYMPTOMS AND DIAGNOSIS

The symptoms in these cases are not unlike those of severe laceration or extreme prolapse except when strangulation takes place, as it did in a number of cases. The doctors reporting strangulation during labor seemed to think the character of the pain was so different from that of labor pain that a diagnosis should be made.

The greatest difficulty in diagnosis is the rarity of the condition, which is evidenced by the fact that so many of the patients were operated upon for other conditions before the true diagnosis was made. In our two cases, the diagnosis was easy because a large tumor was present containing intestines which could easily be reduced and a large defect was felt in the vault of the vagina.

TREATMENT

Palliative treatment such as use of supports is of no value at all in these cases. The only treatment is operation. The procedure should be determined in each individual case.

In the true vaginal type, the best method to pursue is the two-stage operation. Whether the vaginal or the abdominal portion should be done first should be left to the discretion of the operator. We did one each way. Dr. Masson waited three weeks for the vaginal operation in one of his cases, which undoubtedly was good judgment.

In some of the perineal types, a one-stage operation does very well if the sac can be freed and tied off high up and the rectum and the vagina sutured together.

In the complete pelvic type occasionally a vaginal hysterectomy with high perineal repair might be sufficient.

SUMMARY

1. Vaginal hernia is a very rare condition.
2. Care should be taken in examining gynecological patients not to overlook a complicating hernia.
3. The cause undoubtedly is twofold: congenital and traumatic.
4. The classification is difficult because of the adjacent pelvic structures.
5. The symptoms are not characteristic except in case of strangulation.
6. The only treatment is operation.

THE PHYSICANS' COÖPERATION IN PUBLIC HEALTH ADMINISTRATION*

F. E. Harrington, M.D., Commissioner of Health
Minneapolis

A REVIEW of the program for this, the Sixty-Second Annual Session of The Minnesota State Medical Association, furnishes perhaps the best reason for a paper of this title. There are two factors in the program which makes a public health discussion advisable. The first one is the program of the Monday evening session on the economic trend of medicine, and the second is the almost entire absence of any public health paper on the program.

Public health as a legal entity has been with us since early colonial days. Public health as a philanthropy, more properly public welfare, has been the physicians' contribution to humanity from the dark ages. The modern trend in the healing arts is making public health as a legal factor more of an entity than it was in the days when public health was included in the province of medicine. Public health as constituted by law no longer limits its application to the medical field. It must deal with subject matters beyond the practice of medicine and in its contacts and relationships recognizes the legal responsibilities imposed by law on the so-called irregular practitioner. Legislative acts throughout the country recognizing the practice of osteopathy, chiropractic, and naturopathy have given to these schools of practice the same rights and privileges from the public health standpoint as have always been enjoyed by the physician in medicine. The chiropractic law of Minnesota passed by the 1919 Legislature has in it the following:

> "Chiropractors shall be subject to the same rules and regulations, both municipal and state, that govern other licensed doctors or physicians in the control of contagious and infectious diseases, and shall be entitled to all rights and privileges of other doctors or physicians in all matters pertaining to the public health."

The very phraseology used in this paragraph of the law definitely presupposes that there are rules and regulations, both municipal and state, that govern physicians in their practice with its relations to the public health. It is the interpretation and application of these rules and regulations, including of course the legislative acts and municipal ordinances, that constitute the grounds for misunderstandings that so frequently occur between the practitioner on the one hand and the administrator of public health on the other. The time has come, in fact the time has been with us for many years, when public health must be accorded its legal, moral, ethical, and just status. Too long has public health been tolerated rather than supported.

The Women's Auxiliary of the American Medical Association in their program now before our State Public Health Education Committee offers rather a striking outline of activity leading to the proper recognition of the public health. There are five fundamentals upon which this program is based. I would, had I it in my power, add a sixth and very important fundamental. My sixth fundamental would read, "Recognition of the fact that no health department of whatever kind can do effective work without the intelligent coöperation of the medical profession."

In the economic strain of today the profession is looking for a means to equalize the demands of the public. It sums itself up in this phrase: private practice versus state medicine. The public health field must be distinguished from the field of public welfare. Public welfare is public relief and medical care of the poor. Not being public health it will not be discussed here. There can properly be no argument that the field of public health is leading to state medicine. Public health is an activity constituted by law and controlled by limitations of the law enacted for the protection of all the people. It is believed, however, that public health stands as a sentinel to safeguard the public in matters beyond the ability of the individual physician or group of physicians. To the end that public health may be judiciously administered the medical profession as a body must support it. It seems to me rather a travesty on the medical profession's support of the public health when we glance at the figures of the recent meeting of the American Medical

---

*Presented at the annual meeting of the Minnesota State Medical Association, Duluth, July 16, 1930.

Association in Detroit. Of a total registration of 5,104 only 167 registered as affiliated with the section on preventive and industrial medicine and public health. If this is indicative of the profession's interest then certainly public health must take its stand alone, for it is required by law to carry on. A division of interest, however slight, between the two great factors, the practitioner of medicine as an agent of private health, and the directors of health as agents of the public health, will result in a material loss to both sides and to the public.

An active campaign for the support, appreciation and understanding of public health must be started. This session of the State Association, representing as it does medicine in all its branches, should not do less than to actively support a strong, properly organized, properly equipped, and financially supported central health agency for the State. Minnesota with its two and one-half million population deserves the protection which a strong State Board of Health can give. Our State is not keeping progress with the march of events in central health control. The progressive West is far behind the East in this matter. Minnesota is sadly in need of the county unit of health administration. The present system of township health unit dates from the territorial days. In municipalities public health administration is as important as any other phase of municipal government. It should be supported by the medical profession. The functions of state, county, and municipal health in engineering, laboratories, epidemiology, vital statistics, and abatement of nuisances are functions for the best interests of all of the people. It is beyond the province or the power of the medical profession to safeguard water supplies, milk supplies, to safeguard meats and other food supplies for the masses, to provide and execute control measures in communicable diseases, to conduct laboratories and make epidemiological studies, and to collect and tabulate statistics. Until these facts are understood and appreciated public health must function as an activity seemingly not in accord with the practitioner.

All seasons have been open seasons for public health departments. Many physicians consider it their duty to safeguard the patient rather than the public often in a manner contrary to the laws laid down, but there can be no misunderstanding of the paragraph quoted above. There are unquestionably obligations imposed upon the physician who practices his profession by right of state license. A license is a privilege and withal a protection, but carries with it certain obligations and duties, for the law creating the license is no stronger than the law creating limitations. The rights of the individual can never be made greater than the rights of the masses, and the public health workers are for the protection of the masses. The physician who falsifies a record of birth to hide a crime or for the presumed or alleged interest of his patient, the physician who falsifies the records of death for the presumed benefit of a bereaved family at the expense of a life insurance company, the physician who conceals the existence of a communicable disease because of the supposed inconvenience to the patient and family, or who deliberately fails to diagnose a reportable disease, notably tuberculosis and venereal diseases, or who permits infected children to mingle with other children, is no better than the criminal armed to commit murder, or the drunken automobile driver irresponsible for the results of his negligence. If the laws of public health in the State of Minnesota are wrong it is within the province of this Association to rectify them. If the laws on public health in the State of Minnesota are just and reasonable then it should be the duty of this Association to encourage and counsel compliance with them. A definite stand on law enforcement for the protection of the public health is a positive act.

It has been the policy of the Minneapolis Department of Health to limit its activities as much as possible to the things that could not be done by the individual physician. In the administration of the public as well as the school health every possible means has been taken to place in the hands of the physician those duties and functions which are properly his. The Health Department maintains no field physicians for the check-up of the diagnoses made by the family physician in communicable diseases. The Health Department does not stand forth with a big stick but conducts its activities as a coöperative measure doing for the public what the public laws demand, the things that the private practitioner cannot perform. The school health activities are discovery and not corrective. Because of the opportunity presented at a time when children are by law congregated and under discipline, existing defects are looked for and reported only in group. All of these activities result in sending to the physician those patients for the correction of conditions either retarding or mitigating against the future growth of the child. It is disheartening to say the least to find the physician who scoffs at all of the work the public health departments are putting forth, who finds fault with the methods of weeding out and sending to his office the school children needing professional attention, or who takes it upon himself to misinform his families of the requirements of quarantine. Happily, these physicians are in the great minority, but I am convinced that it is possible through the efforts of the Association and its components, the county societies, to make public health a business of the community with the support of the fraternity and with a benefit to the people at large.

May I invite your attention to the first article in the Journal of the American Medical Association, Volume 94, Number 15, April 12, 1930?

A SUMMARY OF THE RECORDS OF SIXTY-FIVE CASES OF RECOVERIES FROM LEPROSY

A report recently issued by the Public Health Service gives an interesting summary of the value of medical treatment for leprosy at the National Leprosarium, which is conducted by the Public Health Service at Carville, La. More than 300 lepers, men, women, and children, are under treatment there.

During the past ten years, 65 lepers have been discharged from this hospital as apparently recovered from leprosy and no longer a menace to the public health. The average period of hospital care varied from 5 to 9 years. The shortest period of treatment was 1½ years and the longest was 17 years. Fifty-five of these patients received crude chaulmoogra oil by mouth, and sixteen of this group received no other medicine. Twelve received benzocaine-chaulmoogra oil by intramuscular injection, and four of these received no other medical treatment. Twenty-one received the ethyl esters of chaulmoogra oil by intramuscular injection, and eight of these received no other medicine.

The basic treatment of leprosy is similar to that for tuberculosis, and all lepers at the National Leprosarium, no matter what medicines are given, follow a sanatorium of food, fresh air and rest, almost identical with that prevailing in a tuberculosis hospital.

ROENTGEN DIAGNOSIS OF SYNOVIAL ADHESIONS

Another chemical adjunct to roentgen diagnosis seems to be available. With this new aid, altered permeability of synovial membranes can be determined and accurate pictures secured of synovial adhesions. This substance is a disodium salt of tetraiodo-orthosulphobenzoic acid. The substance is reported to be relatively non-toxic and to be well borne when injected. (Jour. A. M. A., December 6, 1930, p. 1749.)

ORAL IMMUNIZATION AGAINST PNEUMOCOCCI

Thus far, laboratory studies concerning oral immunization against specific infections have not been encouraging. Most of the suggested oral vaccines apparently are rapidly destroyed or denatured in the gastro-intestinal tract. Oral immunization will presumably be limited to the relatively few vaccines sufficiently resistant to gastro-intestinal denaturization. The most resistant group of micro-organisms are apparently the pneumococci. Recently, successful oral vaccines against pneumococci are reported to have been developed by Dr. Victor Ross. It is to be hoped that Ross's encouraging researches will not be handicapped by premature clinical or commercial exploitation. (Jour. A. M. A., October 4, 1930, p. 1024.)

PERMANENT DISABILITIES OF THE EXTREMITIES*

A PROPOSED RATING SCHEDULE

Myron O. Henry, M.D., F.A.C.S., and Edward T. Evans, M.D., F.A.C.S.
Minneapolis

SURGEONS vary greatly in their estimates of certain permanent disabilities of the extremities submitted to State Industrial Commissions, and often confusion and unnecessary litigation follows. The tentative schedule presented herewith is intended to help clarify the present unsatisfactory situation. Completeness and details have been sacrificed for the sake of brevity. The ratings are purposely high in favor of the claimant in the hope of stabilizing a maximum rating for the specific disabilities. Each state has its own law, of course, but the disabilities are constant, and bear the same relative loss of use to the individual under any law. The following schedule considers *objective* findings only, but the rating might be varied up to 10 per cent of the specific disability percentage to cover *subjective* complaints of pain.

These ratings are based on the *dexterous* extremity, *i.e.,* the right arm in a right-handed individual, or the left arm in a left-handed individual, and the rating should be reduced by 10 per cent of the specific disability percentage for the non-dexterous extremity.

All ratings are given in percentage loss of use of the extremity as a whole. The basis for the arm, *e.g.,* is complete loss of use — amputation at the shoulder (or with too short a stump to permit a useful prosthesis). Loss of an extremity is usually defined by the various state laws (*e.g.,* Minnesota Law allows 66.33 per cent of 200 weeks pay for complete loss of an arm). Loss of motion is rated according to the percentage of normal range lost —the ratings given herewith covering complete loss of normal arc. We recommend the use of instruments of precision in arriving at an estimate of the degrees of joint motion lost.

Multiple disabilities of an extremity are rated as the sum of the individual joint disabilities, the maximum not to exceed loss of the extremity.

Disfigurement is not compensable unless so serious as to materially affect employability of the injured.

Disabilities of nerves and muscles are referred to the limitation of arcs of active motion of joints involved, except as special nerve injuries obviously require additional coverage.

UPPER EXTREMITY

The upper extremity includes the shoulder girdle. Total loss of the upper extremity is usually defined by local state law.

I. *Sterno-clavicular Joint*

a. Ankylosis b. Chronic dislocation	rate according to resulting loss of active shoulder joint motion

II. *Clavicle*

a. Complete loss b. Non-union c. Mal-union	rate according to resulting loss of active shoulder joint motion

III. *Acromio-clavicular Joint*
    a. Ankylosis—as above
    b. Dislocation
        1. Incomplete (conoid and trapezoid ligaments intact)—5%
        2. Complete (conoid and trapezoid ligaments torn)—rate according to resulting loss of active shoulder joint motion

IV. *Scapula*

a. Malunion b. Loss of blade or body	rate according to resulting loss of shoulder joint motion

V. *Shoulder*
    a. Flail—40 per cent loss of extremity (unless rating for loss of motion exceeds this, in which case rate on loss of motion)
    b. Ankylosis—in Jones position (20° in front of coronal plane, 50° abduction) —60 per cent.

---

*A Committee Report to the Minnesota Orthopedic Club.

c. Ankylosis in bad position—if operable 75 per cent (may be total loss of extremity if inoperable, *i.e.*, patient a poor operative risk)

d. Loss of Motion

1. Loss of elevation (useful arc normally 90° from shoulder level to vertical)—35 per cent
2. Loss of abduction (useful arc normally 90° from side to shoulder level)—80 per cent. Arc refers to any plane and rotation is necessarily limited in proportion and covered in arc loss rating

VI. *Arm*

a. Amputation—at or above elbow—loss of extremity

b. Amputation—4 inches or more below elbow (permitting use of elbow in prosthesis)—85 per cent of arm

c. Shortening—nil unless actually disabling or seriously disfiguring

VII. *Elbow*

a. Flail—Same as ankylosis in good position plus rating for loss of motion

b. Ankylosis in Jones position (at an angle of 110°)—40 per cent

c. Ankylosis in bad position—

1. Acute angle—if inoperable total of arm. If operable, 60 per cent of arm
2. Obtuse angle of 110° to 155°—50 per cent
3. Obtuse angle of 155° to 180°—75 per cent

d. Distortion of carrying angle of elbow (15° valgus)—10 per cent maximum in heavy workers

e. Loss of Motion

1. Loss of flexion beyond acute angle of 80°—not compensable
2. Loss of motion (useful arc normally 80° to 175°)—rated on percentage loss of this range up to 75 per cent maximum

f. 1. Loss of pronation-supination alone (in Jones position, *i.e.*, midway between pronation-supination) — 20 per cent

2. Loss of pronation-supination alone in bad position—30 per cent
3. Loss of pronation-supination alone in Jones position when combined with disabilities of wrist or elbow constitutes an additional 15 per cent disability
4. Loss of pronation-supination in bad position when combined with disabilities of wrist or elbow constitutes an additional 20 per cent disability

VIII. *Wrist*

a. Flail—Same as ankylosis in good position plus rating for loss of motion up to 75 per cent maximum

b. Ankylosis (in Jones position, *i.e.*, at an angle of 135°)—25 per cent

c. Ankylosis in bad position (*i.e.*, straight or in volar flexion)—if operable 30-50 per cent—may be loss of hand if inoperable)

d. Loss of motion—percentage loss of arc (of 25 per cent)

1. Flexion-extension (75 per cent of wrist joint motion)—18.5 per cent of extremity. Useful arc normally 165°
2. Radial and ulnar abduction (25 per cent of wrist joint motion)—6.5 per cent. Useful arc normally 30° each

IX. *Hand*—Total loss—85 per cent of extremity (includes forearm loss to 4 inches below elbow)

Partial loss—rated on loss of finger function

1. Thumb

a. Total loss—30 per cent of extremity

b. Ankylosis in good position (extended in apposition)—20 per cent

c. Ankylosis in bad position—same as total loss if inoperable, if operable 25 per cent

d. Loss of terminal phalanx—15 per cent

e. Loss of metacarpo-phalangeal joint motion—20 per cent

f. Loss of interphalangeal joint motion—percentage of loss of arc of 15 per cent. (Normal mal range 90°)

2. Index finger (first finger)
    a. Total loss—16 per cent of extremity
    b. Loss of one and a half or more phalanges—16 per cent
    c. Loss of terminal phalanx—8 per cent
    d. Loss of interphalangeal joint motion or ankylosis
        (1) Distal joint—percentage of of loss of arc of 8 per cent
        (2) Proximal joint — percentage of loss of arc of 10 per cent
3. Middle finger (second finger)
    a. Total loss—14 per cent of extremity
    b. Other ratings same proportion of 14 per cent as in index finger
4. Ring finger (third finger)
    a. Total loss—10 per cent
    b. Other ratings same proportion of 10 per cent as in index finger
5. Little finger (fourth finger)
    a. Total loss—5 per cent
    b. Other ratings same proportion of 5 per cent as in index finger

The accrued rating for loss of use of more than one finger should not exceed the total loss of a hand as provided above.

LOWER EXTREMITY*

Since most state laws give no definite ratings for disabilities of spine, no attempt has been made to rate the spine or the spinal portion of the pelvis. Ratings on pelvis are covered in this schedule only as the disability limits hip motion, shortening of extremities, or both.

I. *Lower Extremity*
  a. Amputation
    1. Stump of less than 6 inches—100 per cent
    2. Useful stump 6 inches below hip—87½ per cent
    3. Amputation 3 inches or more below knee (useful stump)—75 per cent
    4. Amputation of foot without loss of ankle motion—50 per cent
  b. Shortening**
    1. One inch—no disability
    2. One inch to 2 inches—10 per cent
    3. Two inches to 3 inches—35 per cent
    4. More than 3 inches—35 per cent to 75 per cent

II. *Hip Joint*
  a. Ankylosis in optimum position (15° flexion—10° abduction and slight external rotation or a proportionate increase in abduction dependent on shortening**)—60 per cent loss of extremity
  b. Ankylosis in bad position—75 per cent to 100 per cent if inoperable
  c. Loss of motion
    1. Flexion-extension (45 per cent of hip motion)—useful arc normally 120° of which flexion is 105°—extension 15°
    2. Abduction-adduction (22½ per cent of hip motion)—useful arc normally 90° of which abduction is 45°—adduction 45°
    3. Internal and external rotation (7.5 per cent of hip motion)—useful arc normally 90° of which internal rotation is 45°—external rotation 45°

Formula: The proportionate part of flexion (45 per cent), plus the proportionate part of abduction (22½ per cent), plus the proportionate part of rotation (7½ per cent), equals the disability.***

III. *Knee*
  a. Flail—75 per cent
  b. Ankylosis in good position (at an angle of 170° to 150°)—60 per cent
  c. Ankylosis in bad position (at an angle of less than 140°—if inoperable)—87½ per cent

---

*Just as in shoulder joint, so in the hip joint, motions are considered with reference to the pelvic girdle as a whole; whereas scapular motion completes the upper extremity to some extent, this does not play so great a part in the lower extremity, except in some fractures of the pelvis, especially of the acetabulum. However, the mobility of the hip joint is so great that the authors deemed it wise to classify these motions with specific values for each, so that the total disability present could be readily ascertained.

**Optimum position depends on amount of shortening. See table of abduction. Jones & Lovett, p. 138.

***In rating the hip, the proportionate loss of flexion should be added to the proportionate loss of abduction and rotation, thus, if two-thirds flexion is lost, the flexion disability will be two-thirds of 45 per cent, or 30 per cent. If two-thirds of abduction and adduction are lost, the disability will be two-thirds of 22.5 per cent, or 15 per cent. With rotation completely lost or 7.5 per cent, the disability of the hip would be the sum of these three figures, or 52.5 per cent.

d. Loss of motion
  1. Flexion-extension—useful arc normally 180° to 75°

(Formula: The proportionate loss of arc of 60 per cent.)

  2. Extension limited to less than 160° —same as ankylosis in bad position
  3. Abnormal lateral mobility—10 per cent to 30 per cent
  4. Relaxation of either or both crucial ligaments and other internal derangements—10 per cent to 40 per cent

V. *Ankle*

a. Flail—50 per cent
b. Ankylosis in good position—25 per cent
c. Ankylosis in bad position (calcaneus or over 20° plantar flexion)—if inoperable—50 per cent
d. Subastragalar ankylosis in good position—15 per cent
e. Partial ankylosis of subastragalar joints (always painful)—35 per cent if inoperable
f. Loss of motion
  1. Dorsiflexion (24 per cent of extremity) useful arc 90° to 70°
  2. Plantar flexion (16 per cent of extremity)—useful arc 90° to 125°

Formula: The proportionate part of dorsiflexion (24 per cent) plus the proportionate part of plantar flexion (16 per cent) equals the disability (*e.g.*, in estimating the disability in ankle motions, the proportionate loss of dorsiflexion is considered as that proportion of 24 per cent, and added to the proportionate loss of plantar flexion which is represented by a total value of 16 per cent.)

g. Loss of the foot
  1. With loss of ankle joint motion—67½ per cent
  2. Amputation proximal to heads of metatarsals (loss of weight bearing)—67½ per cent. (In our experience such amputations usually require rating as for amputations above the ankle or loss of ankle motion)
  3. Loss of metatarsals rated as the proportionate loss of weight bearing (which if total is specified in paragraph 2 as 67½ per cent)
  4. Great toe
    a. Amputation at metatarso-phalangeal joint—10 per cent
    b. Amputation at interphalangeal joint—5 per cent
    c. Loss of motion (hallux rigidus) —15 per cent
  5. Other toes
    a. Total loss—3 per cent
    b. Partial loss—1½ per cent

For their kind advice and help in preparing this schedule, the authors extend their thanks to the following: Dr. W. A. Cochrane, Edinburgh, Scotland; Dr. Wallace Cole, St. Paul, Minnesota; Dr. H. E. Conwell, Birmingham, Alabama; Dr. Emil S. Geist, Minneapolis, Minnesota; Dr. Robert B. Osgood, Boston, Mass.; and Dr. Phillip D. Wilson, Boston, Mass.

CASE REPORT

AN UNUSUAL CASE OF HYPERTENSION

Charles Koenigsberger, M.D.
Mankato, Minnesota

This case is brought to your attention because of its failure of classification. Instances of vascular hypertensive disease usually drop quite simply into the proper slot—essential hypertension, glomerulonephritis, toxemia of pregnancy, and the like. Cases may manifest bizarre clinical features, but the classification of the fundamental type is scarcely ever baffling. This case, I believe, is very unusual if not unique.

The patient is a young man, aged 29, by occupation a plumber. During January of this year, while working in St. Paul, he had a severe attack of septic sore throat, at which time cultures showed streptococcus. He went to his home at St. James to recuperate. Shortly after his arrival at home, he had a tonsillectomy performed by his local physician. A few days after this operation, he commenced having very severe upper abdominal colic; so severe, in fact, that his physician considered the diagnosis of biliary or renal colic.

Early in February he came to the Mankato Clinic, and was hospitalized for observation. The striking feature of the examination was a vascular tension of 180/140. The heart was only a trifle enlarged; the rate was rapid and the diastolic sounds were accentuated. The vessel at the wrist showed very little, if any, thickening. The retinal vessels showed a moderate narrowing of the arteries, no notching, and no hemorrhage in either retina. The urine was normal, there being no signs of a glomerulonephritis.

During his stay in the hospital he had repeated attacks of three different types of pain:

1. Abdominal: The pain was severe, cramping in type, and unaccompanied by fever, vomiting, or physical signs of visceral disease.
2. Cerebral. The pain was that of a generalized, very severe headache.
3. Coronary. The pain was that of a typical attack of angina pectoris. Hypodermic administration of a quarter of a grain of morphine with one-hundredth of a grain of nitroglycerine invariably produced immediate relief. The use of nitroglycerine alone has caused immediate cessation of pain, but the relief was very transitory unless the drug was combined with morphine.

About two weeks after admission the patient developed repeated periods of angina and his condition was, in my opinion, critical. At this time I invited Dr. Edwin Bannick of the Mayo Clinic in consultation. Dr. Bannick will recite his impression of this case when I have completed this brief clinical description.

The kidneys at no time gave trouble. The intake and output balanced well. The function as determined by blood chemistry and the phenolsulphonephthalein test was only slightly impaired, and there was at no time evidence of any glomerulonephritis.

The eye grounds remained clear of exudate or hemorrhage. No symptoms or sign of cerebral hemorrhage or thrombosis developed.

The heart gave a great deal of trouble symptomatically. Anginal attacks of extreme severity continued almost daily for about five weeks. The pulse was rapid—the rhythm was of the gallop type. The electrocardiogram showed an inverted T wave in Lead one with a convex ST interval. The patient was given regular doses of nitroglycerine and morphine by hypodermic, and erythmyl-tetra-nitrate and euphyllin by mouth. About five weeks after admission, improvement commenced. The attacks of pain ceased, and the patient went home at his own request on March 22.

I have seen him a few times since. He continues without pain, is gaining weight, and is able to do light work.

During his entire illness, the blood pressure remained systolic 150 to 180 and diastolic 110 to 140, and on April 26th, when I last saw him in the office, the reading was 170/120.

Biopsy of a bit of pectoral muscle was made and will be described by Dr. Bannick.

This, then, is a case of acute diffuse vaso-spastic disease following a streptococcic throat infection, characterized by involvement of the splanchnic, cerebral and cardiac vessels, and escape of the kidneys, the extremities, and the retinæ.

From the first I considered the existence of malignant hypertension, but the lack of retinal findings precludes this diagnosis.

PRESIDENT'S LETTER

I WONDER how many of our members are aware of the importance to us of the Women's State Auxiliary and its affiliated County Auxiliaries.

This well organized and energetic group is also affiliated with the National Auxiliary; has been so affiliated since the very year the National Auxiliary was organized at St. Louis in 1922. Three of its County Medical Auxiliaries, Hennepin, St. Louis and Ramsey, are among the earliest organizations of the sort in the entire United States.

These women, in their thirteen affiliated Minnesota societies and their similar union with other auxiliaries of all but ten unorganized states of the union, have a very simple, a very definite object in view. It is to further the aims and ideals of the medical profession. Have we not, sometimes, rather overlooked these powerful allies of our organization?

Lay health education is a new thing for the doctor, a rather bewildering obligation that modern social and economic developments have thrust upon us. It is probably not strange that we should have had a tendency to wander far afield, tilting at distant windmills.

We have very properly embarked upon newspaper and radio and platform publicity at considerable expense and labor. But it is certainly high time that we also made practical use of our auxiliaries in our program of public health education.

The physician's wife is likely to be a very important person in her community. Often she has a variety of social, charitable and public affiliations. She is interested in Woman's Club work, in cultural groups of all sorts. Her contacts are the sort that the physician himself cannot make except impersonally from the platform or through the newspaper.

It seems to me to be the most obvious and elementary good sense that we should employ an important part of our educational effort at keeping the physician's wife posted on sound public health procedure, on new developments in medicine, on the worth of medical care, on the social problems that face the doctor. Her testimony in and out of her auxiliary organization is more valuable to the cause of medicine than tons of formal exhortation and she is eager to testify.

In Minnesota we have, I am convinced, the most effective, earnest auxiliary organization in the entire United States. At the present time it has thirteen affiliated societies, representing, just as our County Medical Societies do, many more than thirteen counties. But with our assistance and encouragement this number will be very quickly extended.

It is my ambition, in fact, to see an auxiliary established for every component county medical society in our association this year. To this end every member of the association should make it a point to talk over auxiliary possibilities and membership with his wife—urge membership upon her if she is not already a member and assist her to organize a society where there is no society.

In the nine years of their existence, the auxiliaries have been of immense service to our organization but they welcome further coöperation. They ask our advice. LET US USE THEM!

L. Sogge

President
Minnesota State Medical Association.

Vol. XIV February, 1931 No. 2

UNIVERSITY SUPPORT

The question of appropriations for University maintenance and development comes before the legislature at each session. A brief but comprehensive survey of the present situation and the needs of the University has been prepared in pamphlet form by the Regents for the information of those interested. The determining of what constitutes a proper appropriation and the distributing of the available funds each year to meet the demands of the various University departments is a huge administrative task.

The demand for university education has increased tremendously in recent years. If the universities throughout the country continue to grow faster than the nation's population there is bound to come a time when adequate facilities will be available for that percentage of the youth of the country that merits the investment of a university training. It is interesting to conjecture just when that point will be reached. Perhaps it has already come.

Our state university has grown tremendously during recent years. Last year the enrollment increased over a thousand and has now surpassed that of Iowa, Wisconsin, Illinois, and Michigan. Legislative appropriations, however, have not kept pace with this growth. Minnesota suffers by comparison with neighboring state universities. The annual per capita appropriation at Wisconsin last year was $306; at Iowa, $345; at Illinois, $412; at Michigan, $467; while at Minnesota it was but $234.

What must be the result of such a comparatively low appropriation? Unless tuition is increased, the instruction must suffer. Larger classes, poorer professors and instructors and a low morale which always accompanies underpay must of necessity follow. Of course, entrance requirements can always be raised to cut down matriculation.

The so-called private universities depend on endowments instead of legislative appropriations. Millions are added each year to their resources. The present suggestion of the Board of Regents that an endowment fund be established for the University is not new. With the waning in the natural resources of the state in its forests, mines and rich top soil, the ability of the state to care properly for the University in future years is questionable. The suggestion is made that the sum of two and a quarter millions of dollars be set aside yearly for an endowment and the appropriation this year be made on the basis of $252 per student. With this increase of income from endowment it is felt that no increase in appropriations need be made and by the end of a ten year period it is hoped that the biennial appropriation might even be reduced.

The medical school alumni are particularly interested in the welfare of the medical school.

The loss of three outstanding members of the medical faculty recently was, as far as we know, simply an inability to compete with a wealthier institution. This has caused some concern in medical circles but faculty losses from the same cause have not been limited to the medical school.

In the plans outlined for the Medical School in the report mentioned, attention is called to the long standing need for a psychopathic division of the University Hospital. An increase of $75,000 in the present University Hospital appropriation of $300,000 (half of which is borne by the various counties) would fill the hospital and reduce the waiting list of indigent patients throughout the state. The Anatomy building and Millard Hall will sooner or later need additions. Eventually the two blocks across the street from Millard Hall and the University Hospital will have to be acquired for medical school purposes and then a building to be used in training leaders in Public Health is needed and according to estimates will cost about $150,000.

We have a fine University. To maintain it as one of the best in the country requires financial backing, and devotion on the part of its graduates. Last year gifts from friends, alumni and commercial concerns to the University for various university activities amounted to a half million dollars. This was more than has been usually received as gifts by the University. The object is most worthy and the practice should be encouraged. The legislature will do its part and the combined efforts of alumni, legislators, and friends should assure the future of the institution.

THE RECENT QUESTIONNAIRE

The writer ventures this editorial although he may be inviting criticism from some excellent medical workers who may feel that they are misjudged. Apparently the county society memberships are circularized with a series of ten questions relative to State Association and County Society matters, redistricting, the matter of dues, reserve funds, etc.

There can be no doubt that redistricting certain county societies to arrange a membership that is not too small for effective organization (none less than fifty members) seems plausible. Nevertheless, the matter of roads, availability, keen physicians, endowed with scientific aspirations, wholesome discontent and forbearance in the presence of medical polemics—are all very vital in this question of what may develop an effective medical society.

Should the northern and southern medical associations be eliminated in order that the ebbing medical circulation should the more fully circularize the outpost members of the parent organization? This is another evidence of the lament of the A. M. A., and those interested should go back over this journal's editorials for one by this writer entitled "Our Perturbed Organizers." Much correspondence and not a little discussion arose anent that offering, and the end is not yet!

Question 6—"Are you satisfied with the enlarged program of activities—educational, scientific and legislative—which the State organization has engaged in during recent years?" The writer is too happy wilfully to wish to be thoughtless or unkind, but an old conviction mounts to a greater and greater certainty that this program is, for the most part, illogical, and quite ignores our social and professional relations with other community groups.

As to increasing dues (which seems unthinkable at this time), or creating further legislative plans or education reserves, if the program itself is ill advised, the danger arises of converting our State association into a political bund, and the question is easily disposed of. The association and its meetings must not be made the occasion (like an automobile show) of exhibiting the most recent models of medical social machinery. This objectivity only interests those who are engaged in the twilight zone between scientific medicine and utopian social exploits, usually involving mankind's reformation as well as exploitation. These movements are presently unpopular. Like Congressmen seeking an extra session, the increasing army in these pursuits betokens the influence of unemployment in terms of college graduates.

E. L. T.

DR. WILLIAM A. JONES

The passing of Dr. W. A. Jones marks a milestone in medical journalism in our section of the country, as it brings to a close his long incumbency as an editor of the *Journal-Lancet*. Although nationally known as a neurologist his name will ever be associated with that of his journal.

To go back to the beginning of medical journalism in Minnesota, it was in June, 1870, that Dr. Alexander J. Stone, then of Stillwater, published the first number of the *Northwestern Medical and Surgical Journal.* After changing ownership this publication was suspended in May, 1874. In October, 1881, Dr. Jay Owens of Saint Paul began the publication of the *Northwestern Lancet,* which in September, 1886, was purchased by Dr. Stone, he becoming the nominal editor. Thus the connection between the *Northwestern Lancet* and the earlier publication begun in 1870. The associate and active editor of the *Northwestern Lancet* during these years of Dr. Stone's ownership was Dr. William Davis of Saint Paul. It was at the beginning of the present century that Dr. Jones began his direction of the *Northwestern Lancet,* destined in 1912 to change its name to the *Journal-Lancet.* That Dr. Jones, a busy neurologist, was able to continue his direction of the *Lancet* for so long a period testifies to his abundance of energy and to his ability. It should be mentioned that Dr. Jones was ably assisted during this period by Mr. W. L. Klein, publisher since 1887 and himself a recognized editor as well as publisher.

At the annual state medical meeting held in 1917 in Saint Paul, a disagreement as to policies proper for a journal representing the state association led to the establishment of MINNESOTA MEDICINE, owned and controlled by the State Association, and to the termination of the *Saint Paul Medical Journal,* which had been in existence since 1899.

Few medical men in Minnesota enjoyed a wider acquaintance than did Dr. W. A. Jones of Minneapolis. Few indeed had such a wide circle of friends—tried and true. A man of strong likes and dislikes, of indomitable energy, Dr. Jones did much to mould medical opinions in the Northwest. The *Lancet* has reflected Dr. Jones during this period of his editorship and the *Lancet* has been admittedly our worthy rival. We are sincere when we say that MINNESOTA MEDICINE has been a better journal because of Dr. W. A. Jones.

HISTORY COMMITTEE

Medical men have often done many things outside their profession. Many have abandoned medicine for business. Some have written poetry; others have entered the political arena and what not. Who was the President of the United States who started to study medicine? Since no President of the United States so far as is known ever was a resident of Minnesota you will not find the answer to the above in our forthcoming book.

To return to the original subject. The man I have in mind entered the army after practicing medicine for twenty years, as a Captain of Infantry; was discharged from the service a Brigadier General and then resumed the practice of medicine and followed it for twenty-one years longer. When our History of Medicine in Minnesota is completed you may read about him and many others who served in the Civil War. Please forward to Doctor Workman whatever scraps of Minnesota medical history you may be able to supply.

J. M. A.

THE GERM-LADEN BUCKET

How queer to me now are the scenes of my childhood;
Just to think of the place I was born, reared and grew
Makes me shudder and break out in cold perspiration;
It's the greatest of wonders I ever pulled through.

The pig-pen, the stable, the manure pile hard by it
From which flies ascended in one steady swarm;
Our food was uncovered, no screens in the windows.
"Why bother with trifles? Flies don't do any harm."

The ditch with the drainage, the garbage, and chickens,
The outhouse all added their quotas of smell.
And right in the middle, with germ-laden bucket,
Was the open-top, ramshackle, shallow, dug well.

The brook and the meadow with grass-bordered puddles
Gave mosquitos the finest of places to breed.
Did they bite us? I'll say so, with vicious abandon.
Sanitation was then our direst need.

In spite of the romance, the rocks and the rivers
Do you wonder we suffered with fever and chills?
But the old country doctor with germs in his whiskers
Dosed us up once a week with physic and pills.

In winter, ah then came the joys of the country!
The windows were nailed shut for once and for all.
Saturday night meant a bath for the entire family
In the moss-covered wash-tub that stood by the wall.

Did we thrive on this life however poetic?
Were we healthy in those fond glamorous days?
There was no disease organic or catching
That missed us in infancy, manhood, or age.

Take your childhood, its pleasures and moss-covered buckets
The simple life joys of which we hear tell.
I prefer middle age, sanitation. and business
And up-to-date science to help me keep well.

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

"PEOPLE IN BUTTONS"

Gilbert K. Chesterton has turned another witty phrase. This one was to the benefit of the medical profession, and every perspiring doctor, trying hard to convey in words just what a medical bureaucracy might mean, will surely thank him.

Mr. Chesterton is reported to have said in Chicago, the other day: "The panel system of medical practise or its allied systems is merely delegation of the practise of medicine to a GROUP OF PEOPLE IN BUTTONS."

That is, of course, what every champion of private medical practise has been feeling and attempting to say about State Medicine ever since that bogie first raised a menacing head in the American social picture. Mr. Chesterton said it in a word.

"I am against people in buttons interfering with the rights of any man," said the famous English philosopher and satirist, expanding his remark in an interview on the British medical situation which should interest every American medical man.

"The theory of the rational modern state is against bureaucracy. The dole is a tragic thing. So is any measure that metes out a perpetual interference with individual rights and free contacts of the citizenry. Which is exactly what the panel system does. It removes from one class of people the right to make free contacts for individual necessities.

"It is an evil thing when you classify and codify and put into a system of law a recognition of employers and employees as variant classes to be so shown under any constitution. It is an evil thing to deprive the poor of the privilege of choice and to make for them a sort of serfdom.

"The world is in danger right now of getting up an intellectual tree through the utterance of too many platitudes," adds Mr. Chesterton wisely. Prohibition is putting America into something approaching that embarrassing position incidentally, he thinks.

"Prohibition," he says, "is an onslaught against private morality and as such a menace to good government."

But it is comforting to note that, in Mr. Chesterton's important and witty opinion, the world and modern rational government is probably not on its way to destruction.

"Already," he says, "the pendulum has begun to swing back. Amusing reform movements are the paradoxical but inevitable companions of an eager plunge into so-called secret, evil things. But even the pornographers are getting tired. They have almost exhausted the possibilities of exploitation of sex.

"And it is interesting to note that there is another side of the question. There is a search and seeking everywhere in the world for religious experience. Even the British newspapers find nothing of more interest to print than stories of religion and religious experience. The world is a right world, but like all that is mortal it is destined to trial, struggle and tribulation."

OF GENERAL INTEREST

Dr. Raymond J. Josewski of Stillwater, Minnesota, was married to Ruth E. Welch, also of Stillwater, Minnesota, September 6, 1930.

Dr. Henry E. Michelson of Minneapolis was elected president of the Chicago Dermatological Society at the meeting held January 21, 1931.

At the annual meeting of the Ancker Hospital staff, January 13, 1931, Dr. E. M. Jones was elected chief of staff and Dr. Philip Donohue was re-elected secretary.

Word has just been received of the marriage of Dr. Elwyn V. Strand of Bayport, Minnesota, to Mary Johnson of South Saint Paul, Minnesota, which occurred July 5, 1930.

Dr. John F. Madden addressed the Blue Earth County Medical Society at Mankato on "Diagnosis and Treatment of Common Skin Diseases," on the evening of January 8, 1931.

Dr. G. E. Schoofs of North Branch, Minnesota, has been appointed Secretary of the Chisago-Pine County Medical Society. Dr. R. E. Hultkrans, the former Secretary, has moved to Minneapolis, Minnesota.

The Minnesota State Medical Association sponsored the evening of December 29, 1930, as part of the St. Louis County Medical Society Colloquium short course. Drs. E. A. Meyerding, N. O. Pearce and L. Sogge were present.

Dr. John R. Spannuth, formerly of the Mayo Clinic, Rochester, Minnesota, and a member of the Olmsted County Medical Society, has announced the opening of offices at Suite 502, Medical Arts Bldg., 230 North Fifth Street, Reading, Pennsylvania.

At the meeting of the Minnesota Academy of Medicine, held January 14, 1931, the following were elected to membership: Drs. Kenneth Bulkley and Moses Barron, of Minneapolis; Drs. John F. Noble, Max Hoffman and Clayton Williams, of Saint Paul; Drs. Irvine McQuarrie and O. H. Wangensteen of the University.

The International Journal of Medicine and Surgery recently offered three prizes for the best papers presented before the American Association of Railway Surgeons. Dr. John H. Rishmiller, Minneapolis, has been awarded second prize—Wilmot Castle Sterilizer—for an essay on "Habitual Dislocation of the Shoulder Joint."

The following letter from the State Board of Medical Examiners gives information of interest to all physicians practicing in the State of Minnesota:

> "The matter relative to incorporating a group of doctors was presented at our Board meeting held December 2, 1930, and the secretary was instructed to advise that the Board absolutely disapproves of a corporation attempting to practice medicine, and that, in the event an attempt is made, it will take such action as it deems necessary under the circumstances to put an end thereto."

The Josiah Macy, Jr., Foundation has made a grant of $7,200 for the year 1931, to be expended under the direction of Dr. Walter C. Alvarez of the Mayo Foundation in the field of gastro-enterological research. The first fellowship made available by this fund has been granted to Dr. Frances Vanzant, who will work primarily on the physiology of gastric secretion in man and animals. There will be an opportunity for another fellow to work on the pathology of the digestive tract including the nerve supply, and for another to work on problems along the borderline between clinical medicine and physiology.

On December 31, 1930, there were 2,064 paid memberships in the Minnesota State Medical Association. The following is a list of the percentage membership in the component county societies:

RANK	COUNTY	PERCENTAGE
1.	Rice County	.92
2.	Meeker County	.89
3.	Watonwan County	.88
4.	Olmsted County	.87
5.	Freeborn County	.86
6.	Scott-Carver County	.86
7.	Kandiyohi-Swift County	.84
8.	West Central Minnesota	.82
9.	McLeod County	.80
10.	Redwood-Brown County	.80
11.	Winona County	.80
12.	Red River Valley	.80
13.	Chisago-Pine County	.79
14.	Stearns-Benton County	.79
15.	Nicollet-Le Sueur County	.79
16.	Mower County	.77
17.	Southwestern Minnesota	77
18.	Blue Earth County	.76
19.	Blue Earth Valley	.76
20.	Waseca County	.75
21.	St. Louis County	.75
22.	Lyon-Lincoln County	.73
23.	Camp Release County	.72
24.	Wabasha County	.71
25.	Houston-Fillmore County	.69
26.	Wright County	.67
27.	Ramsey County	.67
28.	Washington County	.65
29.	Park Region	.63
30.	Hennepin County	.62
31.	Goodhue County	.58
32.	Upper Mississippi	.57
33.	Steele County	.56
34.	Dodge County	.55
35.	Clay-Becker County	.49
36.	Central Minnesota	.42
	AVERAGE PERCENTAGE FOR STATE	.73

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I understand that an instruction sheet for patients with constipation is being used with much success at the University Hospital's Outpatient Department. Please send me information concerning the same.

   Answer.—The Medical Clinic of the Out-patient Department kindly supplied the following information. The instruction sheet is worded as follows: "Chronic constipation is in most cases entirely unnecessary. The seat of constipation is the large bowel, which represents about the last five feet of the intestinal tract. Many symptoms may develop as a result of improper functioning of this tract. The abuse of cathartics, enemas, and irritating foods are often responsible for aggravating trouble there. *Stools*—Most individuals should have one or two normal stools per day. A normal stool is about the size and consistency of a small peeled banana. Constipated stools are usually hard and dry and may be ball-like or pencil-like in shape. An effort should be made to have a bowel movement at a regular time each day. *Cathartics and Enemas*—No medicine of any kind is to be taken for bowel movements. No large enemas are to be used (1-2 quarts). *Diet in Constipation*—The use of the proper fruits and vegetables in sufficient amount is the most important factor in treating constipation. Fruit is to be taken three times daily; cooked fruits are usually preferable to fresh fruits. Some of the best are: prunes, apricots, baked apple, apple sauce, rhubarb, pear and peach sauce. Vegetables—GREEN COOKED VEGETABLES are to be taken in liberal amounts for both the noon and the night meal. Their chief value is that they contain bulk food which will pass into the large bowel and furnish material for bowel movements. Some of the best green cooked vegetables are: spinach, string beans, beets, carrots, greens, squash, peas, asparagus and cauliflower. Cabbage is often undesirable and should not be used in most instances. The fruits and vegetables are the foods which largely regulate the bowel movements and should be taken in the required amounts. This will vary for different individuals. The amount of fruit must not be in excess with too few vegetables. The test of sufficient bulk is whether or not the individual is having daily normal stools. If too much bulk the stools will be loose, which calls for a cut in the amount of fruit being taken. *FOODS TO AVOID*—Bran is an objectionable food as it is too coarse for most human beings. It is usually advisable to avoid ice cold drinks and sweets. Other food may be taken much as desired, the important factor being a sufficient amount of bulk food in the form of cooked fruits and cooked vegetables. Early in the treatment of constipation there may be difficulty having normal stools. If no bowel movement has been had for two days, it is advisable to inject two or three ounces of olive oil or salad oil into the rectum at bedtime and leave in overnight. If no bowel movement has been had by the next morning a 1 pint of clear water enema may be used."

2. *Question.*—I have removed a suspected epithelioma from the lower lip of a man 66 years of age, and sent the specimen to the laboratory for examination. If epithelioma, will radium treatment be indicated? If so, when should it be used and how should it be applied? Please discuss the proper treatment of epithelioma of the lips.

   Answer.—If a positive diagnosis has been returned and the lesion has been widely excised (V incision), nothing further need be done to the lip. At the University Hospitals and many other places throughout this country routine resection of the nodes of the neck is made in cases of epithelioma of the lower lip. Another treatment which is sometimes used, especially by radiologists, is radiation of both the primary and the nodes. In our experience, the best results are obtained when the lip is either radiated or widely removed by a "V" incision and the nodes of the neck are resected.

3. *Question.*—I would like to get some information as to the relative merits of diphtheria toxoid and toxin-antitoxin in the prophylaxis of diphtheria. 2. What is the youngest age that it is advisable to give either for the prophylaxis of diphtheria? 3. I would also like to have an opinion as to the merits of the new Dick six dose prophylaxis against scarlet fever and the advisability of giving it to babies of one year of age. 4. I am taking care of some babies who are now in apparently perfect health, and wish to advise the parents as to prophylaxis against the various diseases. Would it be advisable to give 11 months old babies prophylaxis against diphtheria, scarlet fever, and smallpox at this time?

   Answer.—1. Diphtheria toxoid and toxin-antitoxin are equal in value as far as prophylaxis is concerned. In addition toxoid does not have the danger of possible anaphylaxis. 2. The youngest advisable age to give either for the prophylaxis of diphtheria is six months. It is usually recommended at the ninth month because natural immunity runs out at this time. Any time within the first year is all right; nine to twelve months is usually the recommended time. 3. Prophylaxis against scarlet fever has not been popular. The probable reasons are: failure to guarantee any sort of result, and secondly the severe reactions which frequently occur. If parents would have it given to their children with these reservations, I see no harm in offering it to your patients. 4. The 11 months old babies should be vaccinated at once against diphtheria, using toxoid. Give the injections one week apart, either three or four, and on the last injection vaccinate the girls on the lower leg, and the boys on the arm against smallpox. It is not necessary to do a Schick test for at least six months. After that, if the parents still want to have the scarlet fever done, it could be given. It is recommended that you give them in this order—diphtheria, smallpox, then scarlet fever.

4. *Question.*—I have a patient with trouble in her pelvis. The history is as follows: She is about

(Continued on page 191)

OBITUARY

Theodor Bratrud

1873-1930

Dr. Theodor Bratrud, pioneer surgeon of Warren, Minnesota, died suddenly at his home December 6, 1930.

Theodor Bratrud was born at Fountain, Fillmore County, Minnesota, February 14, 1873. He received his early preliminary education at Spring Valley, Minnesota. He graduated from the University of Minnesota in 1898 with the degrees of Bachelor of Arts and Doctor of Medicine, and immediately came to Warren, Minnesota, where he practiced until his death. Besides the countless number of friends, Dr. Bratrud leaves to mourn six brothers, namely, Christ of Sioux Falls, South Dakota; John and Oscar of Tacoma, Washington; Albert of Spring Valley, Minnesota; Edward of Warren; and Arthur of Minneapolis, Minnesota.

Coming to Warren in 1899 after finishing his course in medicine, Dr. Bratrud availed himself of the opportunities in the then young Red River Valley and through conscientious study and painstaking work earned for himself a reputation, not only locally but also nationally. In 1904 he founded the Warren Hospital, with which institution he was connected until late in 1926, since which time he has operated an independent hospital and clinic. His associates in this field were Dr. Edward Bratrud and Dr. David Berge. Dr. Bratrud's latest great deed was the founding of the new St. Luke's Hospital in Thief River Falls, Minnesota. He was to have been chief of staff of this new $100,000 structure.

The doctor had added to his early medical education by post-graduate work in Europe in 1904 and 1927, and also by attending all the leading clinics in the United States at regular intervals. He was a member of the Red River Valley Medical and Minnesota State Societies, Minnesota Academy of Medicine, and American College of Surgeons. He was also councilor and member of the Credentials Committee of the American College of Surgeons. He contributed many original and splendid articles to the medical literature. He belonged to several fraternal and social organizations, including the Masons, the Shriners, the I. O. O. F. and the Minneapolis Athletic Club. He was a physician and surgeon for the Soo Line.

During his long years of highly successful practice Dr. Bratrud showed much unselfishness through philanthropical gifts. "There are few men in the Northwest who have contributed so much to Church and State as Dr. Bratrud has." "In the passing of Dr. Bratrud we have lost in him one of America's great surgeons."

Resolution of the Red River Valley Medical Society:

WHEREAS, The Red River Valley Medical Society has sustained a loss in the death of our colleague, Dr. Theodor Bratrud, one of the pioneer doctors and one of the pioneer members of our society, who departed this life on December 12, 1930, at Warren, Minnesota.

WHEREAS, he was one of the leading surgeons of his community and the Northwest, deeply interested in the advance of scientific medicine, charitable to the poor and to the Church, and always ready to aid in all those things that were for the betterment of the profession.

THEREFORE, BE IT RESOLVED, that we, the members of the Red River Valley Medical Association, express our appreciation for the years of devoted service and fellowship and extend to the saddened family the sympathy of the society.

RESOLVED, that a copy of this resolution be embodied in the minutes of our society, and that a copy be sent to the family as a tribute in memory of our colleague.

J. F. Norman, M.D., *Chairman,*
H. H. Hodgson, M.D.,
C. L. Oppegaard, M.D., *Sec'y-Treas.*

Dr. William A. Jones

1859-1931

Dr. William A. Jones, well-known neurologist of Minneapolis, died at the Northwestern Hospital on January 15, at the age of seventy-one. Dr. Jones was not only one of the pioneer Minnesota physicians but he was one of the first physicians in Minnesota to specialize in neurology. As editor of the *Journal-Lancet* since 1901, Dr. Jones has also been actively identified with medical journalism in the Northwest.

Born at St. Peter, Minnesota, in 1859, Dr. Jones came of Scotch and Welsh ancestry and both of his grandsires were soldiers in the Revolution. His parents came west in the early days and braved the dangers of frontier life in Minnesota.

After attending grade and high school in St. Peter, Dr. Jones first studied the drug business in his father's store. Later he took up the study of medicine at the University of the City of New York, where he graduated in 1881. After graduation he became assistant physician at the State Hospital for the Insane at St. Peter.

From 1883 to 1886, Dr. Jones practiced in Minneapolis. After his marriage in 1887 to Annie R. Johnson of Denver, he went with his wife to Europe, where he took special work in the study of nervous diseases, in Berlin and Vienna. Upon returning to Minneapolis he limited his practice to nervous and mental diseases and became clinical professor of this specialty at the University.

At various times he was president of the American Neurological Association, the Minnesota Academy of Medicine and the Hennepin County Medical Society. From 1905 to 1917 he was president of the Minnesota State Board of Health and in 1914 was chairman of the section of nervous diseases of the American Medical Association. In 1928, as vice president of the American Medical Association, he was very active in planning the convention of that body in Minneapolis. Dr. Jones was a member of the Westminster Presbyterian Church, the Minneapolis, University, and Minikahda Clubs of Minneapolis, and the Minnesota Club of Saint

Paul. He is survived by his wife and a sister, Mrs. J. W. Bell, of Minneapolis.

Dr. Fred A. Swartwood

1860-1930

Dr. Fred A. Swartwood, a practicing physician in Waseca, Minnesota, for a period of forty years, died at his home, Wednesday evening, November 12, 1930, aged 69 years. Death followed a year's illness and was due to heart failure.

Born at Cannon City, Rice county, on December 8, 1860, Dr. Swartwood was a son of the Hon. Henry A. Swartwood, who came to Minnesota in 1857 and later served in the legislature Dr. Swartwood attended the public schools of his district, took a four year course at Carleton College, Northfield, and graduated from the Medical College at Ann Arbor, Mich., in 1886. His marriage to Miss Ida M. Poe of Northfield took place on November 20 of that year and they came to Waseca to make their home the next month.

Dr. Swartwood was active in Republican politics, serving as party leader in the county, and was postmaster under the administrations of McKinley, Roosevelt and Taft. In 1920 he was elected mayor and was re-elected for the two succeeding years. During this time he instituted the movements resulting in the building of the Waseca Memorial Hospital.

He enjoyed a wide popularity among railroad men and had served as physician and surgeon for the C. & N. W. Ry. since the war. He was always a hard worker and was capable of performing an immense amount of labor.

Mrs. Swartwood and a son and a daughter survive. The children are Harold Swartwood of Chicago and Mrs. Mark (Madeline) Moore of Waseca. Two grandsons, Mark, Jr., and Henry Moore; a sister, Mrs. Edward Pike; and a brother, Carlton Swartwood, both of Minneapolis, also survive.

THE PROPHYLAXIS OF COCAINE AND ALLIED INTOXICANTS

A study to determine the efficiency of barbital compounds in the detoxication of local anesthetics has been made. The minimal tolerated and minimal lethal doses of cocaine, procaine and butyn for rabbits were determined without protection and after the administration of various depressants. The depressants found effective and in the order of their efficacy were urethane (ethyl carbamate), chloral hydrate, paraldehyde, barbital, phenobarbital, and isoamylethyl-barbituric acid, the last named being the most effective. The investigators find that there are two types of intoxication into which clinical cases may be divided. One has a prolonged course and death results from primary respiratory failure; the other has a short course and death results from primary cardiac failure. The first type is reproduced experimentally by subcutaneous injection of cocaine, the second type by intravenous injection. Against this second type of intoxication the depressants are valueless. (Jour. A. M. A., December 13, 1930, p. 1839.)

MISCELLANEOUS

A SATISFACTORY METHOD OF OBTAINING PROSTATIC AND SEMINAL VESICULAR SECRETIONS FOR BACTERIAL STAINING

William P. Herbst, M.D.

Minneapolis

The two most generally used methods of staining prostatic and seminal vesicular secretions for the identification of microörganisms present are: (1) Usual stains of dried secretion films on slides; (2) usual stains of sedimented urine voided immediately following prostatic and seminal vesicular massage.

The results obtained by the first method are uniformly unsatisfactory because the secretion is either washed off in staining or one sees only conglomerate masses of stain with no possibility of identifying the microörganisms through it. This holds true except in secretions which have lost their normal constituents through prolonged and severe infections resulting in the secretion being pure pus.

The results of stains of the urine which has washed the urethra of its expressed secretions are satisfactory as far as identification of the contained bacteria are concerned, but the fact that the urine itself frequently contains microörganisms or pus, or both, makes this method inaccurate.

These methods are in use by all the technicians and physicians in many hospitals and private laboratories questioned by the writer.

A satisfactory method is as follows:

1. Irrigate the urethra with any antiseptic solution desired after complete emptying of the bladder.
2. Massage either the prostate or seminal vesicles, or both, with the finger per rectum, instructing the patient to compress the glans penis so that the secretion will not be allowed to run out until desired.
3. Allow the secretion to run into 4 c.c. of sterile water in a centrifuge tube.
4. Shake the mixture and centrifuge 3 to 5 minutes.
5. Stain the sediment smears by any staining method desired.

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

QUACK DOCTER DENIED CITIZENSHIP BY FEDERAL COURT

"Doctor" George, alias George Garoponlo, alias George Denison Georgeopoulous, who was arrested in St. Paul July 2, 1929, charged with violating the Basic Science Law, and who, on October 7, entered a plea of guilty and was fined $250.00, had his petition for citizenship denied in Federal Court December 22, 1930, by the Hon. J. W. Molyneaux, Judge of the Federal Court.

Investigation by the Government disclosed "Doctor" George had told an entirely different story than the statement of facts to which he plead guilty. The Government requested that Mr. Brist, attorney for the State Board of Medical Examiners, appear in Court at the hearing on the applicant's petition for citizenship.

Immediately at the termination of the hearing Judge Molyneaux denied George's application to become a citizen. Judge Molyneaux informed the applicant that the Court was not admitting anyone to citizenship unless they made a showing of a good moral character and respect for the law.

SCHOOL SUPERINTENDENT SENTENCED FOR VIOLATING THE BASIC SCIENCE LAW

State of Minnesota vs. Edward L. Schmidt

On November 20, 1930, Edward L. Schmidt of the Public School Board at Meadow Lands, Minnesota, entered a plea of guilty before Judge Fesler of the District Court of Duluth, to a charge of practicing healing without a Basic Science Certificate. The defendant has persisted for the past three years in treating people in that vicinity for various ailments. He is not a medical man but apparently possessed some peculiar complex in reference to the practicing of healing. He had been previously warned on two occasions but continued to remain in the business. Mr. Brist, representing the State Board of Medical Examiners, reports finding various medicinal preparations, including chloroform and ether, in his possession, besides a stethoscope, thermometer, artery forceps and other surgical instruments.

Judge Fesler sentenced the defendant to pay a fine of $500 or three months on the St. Louis County Work Farm. The Court stayed the sentence until the further order of the Court. Judge Fesler warned Schmidt that any attempt on his part to practice healing in any way, shape or manner in the future would result in the payment of the fine and serving of the jail sentence. Schmidt has also been acting as Health Officer for three towns in that vicinity and receiving $450 a year for that service. He is to resign as Health Officer immediately.

Mr. Brist reports splendid coöperation from Mason M. Forbes, County Attorney of St. Louis County, and Harry Boyle, Assistant County Attorney. Splendid cooperation was also received from Judge Funck of the Municipal Court of Duluth and Judge Fesler of the District Court.

ARABIAN RHEUMATIC SPECIALIST SENTENCED TO WOMAN'S REFORMATORY AT SHAKOPEE, MINN.

State of Minnesota *vs.* Winchel

Ada Winchel, fifty-one years of age, was sentenced to a term of not to exceed one year in the Women's Reformatory at Shakopee, Minnesota, on December 8, 1930, by the Hon. R. D. O'Brien, Judge of the District Court, St. Paul, Minn. The defendant was arrested November 29, charged with a violation of the Basic Science Law. Mrs. Winchel has been maintaining an office at 308 Pittsburgh Bldg., St. Paul, without a license to practice healing. She held herself to the public as an Arabian Rheumatic Specialist. She was arrested following the diagnosis of a case as rheumatism and offering to cure the same in four months time. The defendant told the Court that she had been getting her Arabian liniment from Mohamet Nackley, alias "Doctor" Muckly, who on December 9, 1929, was sentenced to one year in the State Prison at Stillwater, Minnesota, for receiving the earnings of a prostitute. Nackley had his place of business at the Superior Hotel, 379 Jackson St., St. Paul. The Court suspended the sentence and placed Mrs. Winchel in the custody of the Probation Officer, on the condition that she close her office and refrain from practicing in any way, shape or manner in the State of Minnesota.

Splendid coöperation was received in this case from Dr. Simon, Health Officer, and Mr. C. D. O'Brien, Jr., County Attorney.

NATUROPATH IN PRACTICE FOURTEEN YEARS SENTENCED

State of Minnesota *vs.* Viger (two cases)

George R. Viger, 45 years of age, with offices at 400 Bremer Arcade, St. Paul, Minn., was sentenced by the Hon. R. D. O'Brien, Judge of the District Court, on December 10, to pay a fine of $200 and to serve a year in the Workhouse for practicing healing without a Basic Science Certificate. The fine was paid and the Court suspended the jail sentence on the condition that the defendant refrain from practicing healing in any manner in the State of Minnesota. It was stated to the Court that the defendant is leaving the State to enter the fruit business in Texas.

Viger was indicted by the Grand Jury of Ramsey County on November 26, on two counts charging him with practicing healing without a Basic Science certificate, in that he treated a patient for diabetes and another patient for goiter. The diabetes patient had been previously treated with insulin but had stopped taking insulin in April, 1930. The patient commenced treating with Viger in July, 1930. On September 21, the patient died at St. Cloud, Minn. The defendant has been engaged in the practice of healing in St. Paul for the past fourteen years. From 1920 to 1927 the defendant held himself to be a physician and surgeon. Recently he has been holding himself to be a naturopathic physician.

Mr. Brist, representing the State Board of Medical Examiners, reports splendid coöperation in this case from C. D. O'Brien, Jr., County Attorney, and Mr. Allen, Assistant County Attorney. Judge O'Brien is to be commended for his stand in insisting that unlicensed practitioners should not be allowed to continue in business and in placing over them a jail sentence of sufficient severity to make it unlikely that they will continue in business.

NATURE OF THE SUBSTANCE IN LIVER ACTIVE IN PERNICIOUS ANEMIA

The search for the "active principle" which renders liver potent in the treatment of pernicious anemia has resulted in the isolation of an active crystalline salt demonstrated to be clinically potent in pernicious anemia. It is a compound of beta-hydroxyglutamic acid and hydroxyproline. Both of these substances possess the characters of protein derivatives; the mode of their linkage remains to be ascertained. (Jour A. M. A., November 15, 1930, p. 1509.)

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over station WCCO, Minneapolis and Saint Paul (810 kilocycles or 370.2 meters).

SPEAKER: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of February will be as follows:

February 4—Humidity in the Home.
February 11—Control of Diphtheria.
February 18—Treatment of Constipation.
February 25—Cancer of the Uterus.

SECRETARIES CONFERENCE

Among the important personages who will be present in St. Paul, Minnesota, for the annual Secretaries Conference at the St. Paul Hotel, February 7, are Drs. E. Starr Judd, Rochester, president-elect of the American Medical Association; L. Sogge, Windom, president of the Minnesota State Medical Association; and Messrs. H. A. Bellows, Minneapolis, vice president of the Columbia Broadcasting System, and Vernon D. Blank, Des Moines, Iowa, managing director of the Iowa State Medical Society.

Dr. E. Starr Judd, Dr. L. Sogge and Mr. H. A. Bellows will speak at the luncheon which is an annual feature of the meeting. Mr. Bellows has chosen for his subject, "The Use of Broadcasting for Misleading and Dangerous Advertising."

The morning session, opening at 9:00 o'clock, will be devoted largely to the interests and opportunities of the County Medical Society. Mr. Vernon D. Blank will explain the Iowa system of the "Care of the Indigent Sick by Contract." A symposium on "Public Health Relations" is to occupy the afternoon session.

CLAY-BECKER COUNTY SOCIETY

New officers of the Clay-Becker County Medical Society are: President, Dr. B. T. Bottolfson, Moorhead; vice president, Dr. J. E. Carman, Detroit Lakes; secretary-treasurer, Dr. J. H. Heimark, Moorhead; delegate, Dr. M. C. Bergheim, Hawley; alternate, Dr. O. O. Larsen, Detroit Lakes; censor, Dr. L. H. Rutledge, Detroit Lakes.

Dr. E. A. Meyerding and Dr. Robert M. Burns, St. Paul, Minnesota, addressed the annual meeting of the society on "Our Public Relations" and "The Trend of Modern Medicine," respectively, at the St. Ansgar's Hospital at Moorhead, Minnesota.

WASHINGTON COUNTY SOCIETY

The Washington County Medical Society met at the Stillwater Club Rooms for the regular monthly meeting, January 13, 1931, with a majority of the members present. Dr. J. B. Carey of the Nicollet Clinic, Minneapolis, was the guest speaker. His subject was "Gastrointestinal Lesions," the etiology, diagnosis and treatment, illustrated by numerous and very fine *x*-ray films.

CAMP RELEASE DISTRICT SOCIETY

Camp Release District Medical Society held its annual meeting in the Legion Hall, Granite Falls, Minn., December 4, 1930. During the business session the following officers were unanimously elected. Dr. J. S. Kilbride, Canby, president; Dr. F. W. Penhall, Morton, vice president; Dr. L. J. Holmberg, Canby, secretary-treasurer.

State Secretary E. A. Meyerding, of St. Paul, then gave a splendid talk on "How the State Association Coöperates with the Lay Organizations of the State," and presented lantern slides showing the new state association office building and the different departments.

Dr. W. A. Fansler, of Minneapolis, followed with an unusually interesting address on "Hemorrhoids and Their Treatment" and held a clinic, giving a practical demonstration of the injection method for ambulatory cases.

The society then adjourned to the Hotel Keegan for the joint banquet dinner with the Ladies' Auxiliary, during which our State President, Dr. S. H. Boyer of Duluth, addressed us in a very entertaining manner on "The General Activities of the Parent Organization."

Dr. Meyerding again spoke for the ladies, emphasizing the value of their organization to the district and state societies.

Meeting was again called to order in the Legion Hall, and Dr. T. A. Peppard, of Minneapolis, gave a most interesting and instructive talk on "Heart Diseases," held a heart clinic, and demonstrated the use of the electrocardiograph in a most practical manner. The Minneapolis General Electric Company had shipped the machine out to Granite Falls for this purpose.

A rising vote of thanks was tendered the distinguished guests for their presence and part in the program, and the meeting adjourned subject to executive call for the spring meeting.

L. J. Holmberg, *Secretary-Treasurer.*

ORAL USE OF OVARIAN PRODUCTS IN MENOPAUSE

Rational as ovarian therapy may theoretically appear to be in some conditions, the actual results are rarely striking and often nil to the careful observer. Extensive clinical experience has failed to establish the value of the desiccated preparations administered orally. The Council on Pharmacy and Chemistry has omitted all desiccated ovary preparations for oral administration because long extended clinical use has failed to demonstrate the efficacy of the marketed brands. (Jour. A. M. A., October 11, 1930, p. 1119.)

WOMEN'S AUXILIARY
Minnesota State Medical Association

President—Mrs. S. S. Hesselgrave, St. Paul
Chairman Press and Publicity—Mrs. E. A. Meyerding, St. Paul
Editor—Mrs. A. A. Passer, Olivia

The various committees of the Women's Auxiliary are at work with an earnest determination to obtain the most gratifying results each in their own particular sphere of action. Mrs. James Blake, chairman of the Organization and Membership Committee, assisted by the three vice presidents, has as an objective the organization of auxiliaries to twenty-four county medical societies and their affiliation to the State and to the National Auxiliaries. No county or other auxiliary may affiliate with the A. M. A. save through the state auxiliary; no auxiliary will be represented at the national convention that has not affiliated with our state auxiliary by March 15. The national fiscal year ends in March and no auxiliary is allowed a representative to the National Convention after the books are closed. If you have friends among the doctors' wives who are not members, tell them of the advantages of our organization, and ask them to join the 12,000 doctors' wives whose interests are closely linked with the medical profession. We must do our utmost to retain our rank of third largest membership in the national organization. Our membership now totals 838.

Mrs. Hugh J. Tunstead, legislative chairman, requests that each county appoint a member for her committee who may be called upon to perform only such service as shall be advised and approved by the Legislative Committee of the State Medical Association under the leadership of Dr. Herman Johnson. The National Auxiliary takes care of the legislation of interest to doctors, in the U. S. Senate and House, through the A. M. A., so our interest centers chiefly in legislation in our own state.

Mrs. Carl Larsen, chairman of the Finance and Budget Committee, is preparing the budget for the coming year.

Mrs. Ben Davis, chairman of Public Relations Committee, is awaiting the program now under consideration by our advisors. Dr. E. A. Meyerding, secretary of the Minnesota State Medical Association, has offered to loan books to auxiliaries for the study of medical subjects in preparation for intelligent discussion of various questions that are brought up at clubs, P. T. A., etc. He will also recommend speakers for meetings on application to him at 11 West Summit Avenue, St. Paul. HYGEIA and EVERYBODY'S HEALTH are recommended by our advisors, and should be placed in reading rooms, hospitals, schools and libraries. We trust that the offer of a double subscription to the above magazines made by the Minnesota Public Health Association in December will spread much truth in our state.

Mrs. E. A. Meyerding, chairman of Press and Publicity, asks that each county auxiliary publish notices of its meetings in the local papers; notices of all State Executive Board meetings, and of the annual meeting; three clippings to be sent to the editor, Mrs. A. A. Passer.

Mrs. A. A. Passer, editor, asks that news of auxiliary activities be sent her each month, not later than the eighth.

Mrs. S. S. Hesselgrave, president, sends the following message:

We have had the pleasure of visiting four of our auxiliaries, namely, Washington County, Rice County, Wright County, and Ramsey County, and during January we are to visit Hennepin and St. Louis Counties. We are impressed with the value of the auxiliary from many points of view. Especially is the spirit of kindliness evident in all these gatherings, and the oft repeated statement that doctors' wives, unlike doctors, have nothing in common, is truly an error, since the wives have one very decided interest and that is *the doctor*. Were the doctors to attend a meeting of any of the auxiliaries they would be convinced of the value of the auxiliary from the standpoint of the common interest of all its members.

The activities of our component societies are noteworthy. The hospitals and various institutions are the recipients of much cheer and comfort and our loans are a boon to the medical student and the student nurse.

The social side is not neglected and the well organized auxiliary can, with perfect ease, entertain hundreds of visitors during a convention, where the lack of an organization of that sort would entail a loss of time and prove a costly experiment. The very gracious hospitality extended by the St. Louis County Auxiliary to our members and to visitors during the annual convention in Duluth last July alone justifies the existence of a Women's Auxiliary.

A copy of the annual meeting minutes was sent to each county president in September, and a copy of the Constitution was mailed to each member of the state auxiliary in November. In December letters were sent to the county presidents asking them to coöperate in the sale of Christmas seals. Please notify us at once after your election of officers so that we may send material to the proper addresses.

At the request of the Women's Auxiliary to the A. M. A. we have asked that three advisors be appointed from the Minnesota State Medical Association, and we are informed that Drs. C. B. Wright, George Earl and E. A. Meyerding will guide us this coming year. May we suggest that local auxiliaries follow this plan? We cannot embarrass our medical societies in any way if we consult them first, and they know what they want their auxiliary to do and when to advise against imprudent actions.

May I solicit your coöperation and suggest that we put our best efforts into our work during the next four months, at the end of which time we must give an account of our stewardship to both the state and the national auxiliaries. The state meeting will be held in

Minneapolis May 3, 4 and 5, 1931, and the national convention will be held in Philadelphia June 8, 9, 10, 11 and 12, 1931.

BLUE EARTH COUNTY AUXILIARY

The Blue Earth County Auxiliary was organized in 1924 and affiliated with the State Auxiliary in 1926. It has a membership of nineteen. Two bridge teas were recently given, the proceeds to be used to sponsor "Hospital Day" at each of the local hospitals. The following officers were elected for 1931: President, Mrs. A. E. Sohner; vice president, Mrs. H. L. Huffington; secretary, Mrs. William Black; treasurer, Mrs. W. C. Stillwell; corresponding secretary, Mrs. John Butzer.

Committee chairmen for the year are: Legislative, Mrs. R. G. Hassett and Mrs. F. W. Franchere; Membership, Mrs. A. V. Denman, Mrs. J. T. Schlessleman; Press and Publicity, Mrs. John Butzer and Mrs. William Black; Social, Mrs. G. A. Dahl, Mrs. A. W. Eckstein and Mrs. A. J. Wentworth.

STEARNS-BENTON AUXILIARY

The Women's Auxiliary of the Stearns-Benton Medical Society has thirty-one state and local members. In December the members met with Mrs. Werner Hemstedt of the St. Cloud Reformatory, at which time a Hospital Auxiliary was organized for the purpose of making sheets and pillow cases for the St. Cloud hospital. The January meeting was held at the home of Mrs. J. E. Dwyer, St. Cloud. Officers for 1931 are: President, Mrs. Werner Hemstedt; first vice president, Mrs. T. N. Fleming; second vice president, Mrs. D. G. Kohler; corresponding secretary, Mrs. J. J. Gelz; recording secretary, Mrs. R. N. Jones; treasurer, Mrs. Jennie Hovorka; auditor, Mrs. J. C. Buscher.

WASHINGTON COUNTY AUXILIARY

On Tuesday, February 3, the Washington County Auxiliary and their husbands will be entertained at supper by Miss Christine Strom, superintendent of Lakeview Memorial Hospital, Stillwater. Speakers will be Drs. Herman Johnson, George Earl and Robert M. Burns.

The January meeting was held at the home of Mrs. E. Sydney Boleyn of Stillwater. Mrs. C. E. Andreassen of Minneapolis, who spent five years in China as the wife of a medical missionary, was the speaker.

Officers for 1931 are: President, Mrs. John W. Stuhr; vice president, Mrs. W. J. Hewson; secretary and treasurer, Mrs. Henry Van Meier.

HEXYLRESORCINOL AS AN ASCARICIDE

Lamson and his collaborators believe that they have discovered an effective ascaricide in hexylresorcinol. According to New and Non-official Remedies, the drug is stated to be relatively nontoxic when administered by mouth. The drug has irritant properties, but these are not regarded as a contraindication for its occasional use and they are transitory in effect. (Jour. A. M. A., November 22, 1930, p. 1592.)

PROCEEDINGS MINNESOTA ACADEMY OF MEDICINE

Meeting of December 10, 1930

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club, Wednesday evening, December 10, 1930. Dinner was served at 7 o'clock and the meeting was called to order by the President, Dr. Emil S. Geist. There were fifty-one members present.

Minutes of the November meeting were read by the Secretary and approved as read.

The following officers were elected for 1931: President, J. S. Gilfillan, St. Paul; vice president, J. C. Litzenberg, Minneapolis; secretary-treasurer, R. T. LaVake, Minneapolis.

The scientific program was as follows:

Dr. Hilding Berglund (Minneapolis) reported a case which had been seen at the University Hospital at various times over a period of three or four years, in which various diagnoses had been made.

DISCUSSION

Dr. E. L. Gardner (Minneapolis): This is an extremely interesting case. I have been following since the spring of 1927 a somewhat similar case. The patient is a nurse, forty years of age, who came into the office with the support of two friends. She had complained of stiffness of the muscles and joints, with various aches and pains which had been recurrent since 1917. In 1921 she began to have diarrhea with six or eight stools a day. She has been having recurrence of the diarrhea and stiffness throughout the body with the approach of spring each year, while in the fall and winter her symptoms were usually very slight. She had given no history of redness of the joints, has no fever and claims that the soreness was generally distributed not to the joints alone but all over the bony skeleton. She had noticed that there was free oil in the stools, which floated upon water. Her diet had always been an excessive vegetable one. She has become extremely irritable, some muscle twitching, and had been considered as a case of nervous prostration.

Upon examination we found a very frail young woman, under ninety pounds in weight. The skin was rather pale, muscles flabby, gait very difficult because of an extreme spasm of the spinal muscles and upper thigh muscles, especially the adductors of the thigh, whenever she attempted to walk. The positive findings were spongy gums with soft teeth, negative chest, and upon examination of the extremities there seemed to be an intense tenderness over the bones upon pressure and not limited to the joints. The muscles were extremely spastic and irritable, although we could not demonstrate any of the symptoms of true tetany. The abdomen showed general tenderness, especially over the colon. The nervous examination was entirely negative. There was no decrease of vibration sense. There was a complete achylia gastrica. The hemoglobin ranged between 50 and 65 per cent but there was no abnormal condition of the red blood cells except hypochromasia.

and the hemoglobin index was well below one. There were no changes in the blood to suggest pernicious anemia. The stools were strongly acid in reaction, of waxy color and contained a large quantity of neutral fat which stained with fat stain. There was also a marked excess of undigested meat fibers and starch granules. The blood chemistry showed a calcium of 8.8, but a normal VanSlyke. The *x*-ray examination showed a normal stomach except for hyperperistalsis and there was hypermotility all along the digestive tract. The gallbladder filled poorly after tetraiodophthalein. One very important feature of the case was that it was almost impossible to show the bone on *x*-ray films because of the lack of shadow-producing quality, which was interpreted as probably due to a withdrawal of calcium phosphate.

The progress of this case was extremely interesting. Since we were unable to make a definite diagnosis as to the condition, but since we believed that many of the symptoms were not due to arthritis but due to decalcification of the bone, and since the patient apparently was losing so much calcium by the diarrhea, we put her on a diet which would produce the nearest normal stools. She was given a diet with restriction of starches, but containing rather large quantities of butter-fat. All the vegetables were finely divided and she was given rather large quantities of protein. She was also given large doses of calcium carbonate and calcium phosphate sufficient to hold down the diarrhea. Under this management, as well as the exposure to sunlight, the stools became formed and free from undigested food particles. Within six months after treatment the patient was able to be up and about and during the past three years has been able to be a public health nurse in one of our largest department stores. She has had no recurrence of her trouble, but is still very careful to maintain normally formed stools as well as maintain her nutrition.

An *x*-ray examination of the bones more recently shows them to be perfectly normal. There was no arthritis and no deformities.

This case also seems to be one of decalcification of the bone, probably secondary to a gastrointestinal lesion which prevented the proper absorption of calcium salts and caused their withdrawal from the bony skeleton. We have in this case a blood calcium slightly below normal which returned to normal after a period of three months. And also we had in this case a muscle irritability and muscle spasm. The VanSlyke was always normal and we could not demonstrate a true spasmophilia.

Both Dr. Berglund's and my case are interesting for speculation, but it seems very probable that the withdrawal of calcium from the body by a chronic diarrhea was an important factor in producing the symptoms.

Dr. James Johnson (Minneapolis) read his thesis, entitled "Acute Mechanical Obstruction of the Lower Bowel, with an Analysis of Thirty-six Personal Cases." Lantern slides were shown.

DISCUSSION

Dr. A. R. Colvin (St. Paul): I am not quite clear as to Dr. Johnson's classification of high and low obstruction. Of course, we all readily recognize the fact that the higher up in the small intestine the obstruction occurs the more dangerous it is. The classification that I like to carry in mind is whether the obstruction is of the large bowel or of the small bowel.

An English surgeon reported all the cases operated on at one of the large London hospitals—over 900 cases. His study led him to believe that it was almost fatal to attempt to do any radical surgery in acute obstruction. Enterostomy, of course, as Dr. Johnson has done it, is a life-saving procedure. In obstruction of the colon from the cecum on, I believe the life-saving procedure is cecostomy. It is sometimes a question as to how cecostomy or enterostomy should be done.

The cecum seems to bear the brunt of the distention; obstruction anywhere below the cecum is attended by greater distention of the cecum than any other part of the large bowel. Indeed, in a neglected case we may find ulcers in the cecum without finding ulcers anywhere else. I think if the cecum is very greatly distended and the patient is very sick, even a little nick made to put a catheter in may allow just enough contents to escape to spoil the whole game and the patient may die of peritonitis.

The procedure I like best is, under local anesthesia, to expose the cecum so that a sufficient area can be used to suture to the peritoneum. If not sewed to anything more than the peritoneum, the opening will almost invariably close. It is difficult to sew this without penetrating the distended cecum, but it can be done and in that manner one can wall off a portion of the cecum enough to definitely relieve the obstruction. It is very rare, of course, that one can't wait a few hours before opening the cecum. It is best to wait 4 or 5 hours if possible, because it is surprising how much gluing of the peritoneum has occurred and there is no danger then of infecting the peritoneal cavity. The relief on opening is almost immediate. It is fatal to try to do a resection in acute obstruction.

The diagnosis of intestinal obstruction in the large bowel is a very interesting subject. For instance, I saw a woman about a year ago who was brought into the hospital with a very high temperature and in a great deal of pain. Her symptoms were those of obstruction existing only a few hours. It is very rare to have an elevation of temperature in early obstruction. However, on giving barium, an obstruction was found in the region of the splenic flexure. Cecostomy was done at once and the patient relieved. On account of the location of the obstruction it was thought that it was due to carcinoma. After relieving these patients by cecostomy, there is no hurry for further operative procedures. A few weeks do not mean much compared to the safety of the patient insured by giving the bowel time to recover its tone. Later on, in this woman's case there was found to be a carcinoma of the splenic flexure and the temperature, I believe, was due to an infected carcinoma. I believe this is comparatively common in carcinoma of the colon. In carcinoma of the colon the supervening obstruction is often due to an inflammatory thickening superimposed upon the carcinomatous region. After the relief of the obstruction, it takes quite a while for this edema to subside, but it frequently does. In this particular case the conditions were interesting because about a week after I had done the cecostomy she complained one day of a good deal of pressing down pain in the rectum. I had examined her digitally after relieving her by cecostomy and the rectum was empty, but later, at the time of the complaint of rectal pain, I found that she had a fecal impaction in the rectum. Following the cecostomy the relief of the edema had been sufficient for the feces to travel through the carcinomatous mass and fecal impaction occurred. Undoubtedly in these narrow strictures due to carcinoma the liquid content of the upper colon can seep through the stricture and, becoming inspissated lower down, become well-formed masses.

Dr. A. T. Mann (Minneapolis): I want to compliment the essayist on the very fine way in which he has handled this subject and given us his observations. I notice in the list of his chemical changes of the blood, that he has acidosis down. It seems to me that in nearly all the cases in which vomiting has occurred to an extent to produce chemical changes, we have an alkalosis, which is a much more dangerous thing than acidosis itself. We have, with these changes, the kidney changes shown very definitely in the blood chemistry by a high urea content and often by albumin and casts. So that we have two or three different things to consider in deciding on the treatment for an intestinal obstruction: there is the obstruction itself, and what we shall do for the toxemia, the dehydration, the alkalosis and high urea percentage. The sodium chloride in the water has seemed to have a marvelous effect in straightening out these conditions. It helps the dehydration of course, and it has a very marked effect on the alkalosis.

It is more of a problem just what the glucose does and, as nearly as I can get at it, its effect on the kidney itself is to help the kidney straighten out by its diuretic effect, because if we have an alkalosis it is not logical to put in sugar for the alkalosis itself, so it certainly must do something else, and its effect on the kidney in helping it to do its work better may explain some of its value.

In the operative field, in the late cases we must be very careful about limiting the extent of surgery as much as possible. Enterostomy should be employed more than it is and, in the later cases, very often nothing else should be done. Holden not only does that in practically every case, but he disembowels the patient and with the aid of an assistant he actually strips the bowel, from the top down, between his fingers, which he first smears with vaseline. But that never seems to me quite a proper surgical procedure on account of the shock. We know that the handling of the bowel is one of the things which causes shock in a most marked degree so that I believe that surgeons in general do not think it is best to do it.

I think the essayist is greatly to be congratulated on his work.

Dr. A. E. Benjamin (Minneapolis): I have been very much interested in this paper. It seems to me the first thing one should do is to make a diagnosis of where the obstruction is and what the causes are. We know that if the obstruction is in the small bowel the treatment is different than when in the lower bowel. If due to bands of adhesions in the ascending colon, a right-sided incision (as in appendicitis) relieving the obstruction is all that is required. If the obstruction is in the descending colon or sigmoid due to diverticulitis, the treatment must necessarily be different. When due to diverticulitis or carcinoma of the sigmoid or colon, a colostomy may be necessary. In certain forms of diverticulitis producing acute obstruction a colostomy may be done by simply bringing the colon up through the abdominal incision, passing a fascial strip through the mesentery for support and when the inflammatory obstruction subsides this strip may be cut and the colon replaced in the abdomen. The colostomy will narrow as the colon functions or it may be closed by an operation.

If there is much vomiting, a gastric lavage should be performed at frequent intervals to remove the toxic substances. When the bowel is distended from gas and contents, there is a transmigration of infectious microorganisms through the walls of the intestines and a peritonitis may supervene. The gastric lavage reduces the distention and the patient may be relieved of the obstruction. Regurgitation of infectious material in the bowel to a higher level which the upper intestinal tract is not used to harboring may be responsible for a toxic state. In case of a distended cecum, I prefer to use a hypodermic needle of large caliber to empty the colon of the gaseous material, when the bowel may be brought up into the wound and a cecostomy more easily performed. Washing the bowel out at frequent intervals through a colostomy opening reduces the toxic substances and overcomes the distention. It also prevents dehydration.

If we can make the diagnosis in the first place our incision can be made with more certainty of overcoming the condition. Resection, of course, should be performed only in old chronic small carcinoma, simple obstructive cases or acute mesenteric thrombosis.

Dr. Johnson (in closing): I wish to thank all of the doctors who took part in the discussion of this thesis.

Dr. Colvin's question in regard to the classification of high and low obstruction is undoubtedly well put. The obstructions reported here are all in the lower ileum and colon. High obstructions would be considered those in the pylorus, duodenum and jejunum. I do not know that one can draw an arbitrary line as to what would be high and what would be low except from a general understanding. Dr. Colvin and Dr. Mann both mention cecostomy in the presence of obstruction from malignancy in the colon. The cases reported here causing obstruction were all in the descending colon where they could be brought out and a tube put in the proximal loop. However, as a general rule, it is very necessary before ever attempting a resection of a malignancy in the colon to do a primary cecostomy and allow the patient to overcome all of the symptoms of an acute obstruction before attempting the major procedure.

The blood chemical changes in the reported cases have, I believe, almost entirely been alkalosis. In fact, it is very rare now that one ever sees any marked chemical changes of either alkalosis or acidosis, because they occur only in neglected cases. Dr. Mann mentions the danger of stripping the bowel in cases of obstruction. There are some cases in which this can be done to great advantage, but it should be done with a great deal of care. In other cases, where the bowel is very friable and where undoubtedly leakage has occurred, it is no doubt advisable not to do this procedure. I believe this should be left, like many other things, to the individual judgment of the surgeon.

Owing to the lateness of the hour, Dr. F. E. Burch, who was to give a paper on "The Operative Treatment of Squint by Tucking Method," asked that this be postponed to some future meeting.

The meeting adjourned.

R. T. LaVake, M.D., *Secretary.*

(Continued from page 182)

45 years of age. In May, 1928, she had a breast amputation for cancer. In November, 1928, she was in an auto accident. After getting out of the wreck, she was able to walk down the road about two blocks, but has never been able to walk since. The right leg has shortened about 3 inches. Following the accident she has been confined to bed, lost weight, been unable to eat, has pain in her sacral region, in right hip and leg and in left iliac crest. She has a mass in the left epigastric region the size of an orange that is fairly firm and irregular in outline. I saw her first in April, 1930. At that time she was taking morphine gr. ½ every 3-4 hours, was very emaciated and anemic, was vomiting. I expected her to die within a few weeks. I did not see her again until July 18th. She has gained weight, is eating well, is taking morphine only twice a day, says she feels good except for considerable pain in her sacrum. She tells me that since April she has been taking 3 drams of whiskey three or four times a day and she attributes her improvement to that. The *x*-ray shows a fracture neck of the femur and carcinoma. Some one has told her that her trouble is tuberculosis of the bone and that the prognosis is not fatal and that she ought to recover.

Answer.—The moth-eaten appearance is diagnostic of metastatic tumor from the breast. The change in the left hip suggests either an old fracture or more likely a purulent arthritis with destruction of the head of the bone and part of the acetabulum. There is nothing about the case which suggests tuberculosis. We have found that the treatment of metastatic tumor of the bone very often should be given in this order: Deep *x*-ray first, and if this does not succeed, follow with morphine. We have had some very startling results with prompt and temporary relief of pain by deep *x*-ray treatment. It might be possible, if the patient's condition warrants it, to try the effect of this treatment if she still complains of pain. Morphine should be the treatment of last, not first resort.

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

Meeting of December 4, 1930

The regular monthly scientific meeting of the Minneapolis Surgical Society was held in the lounge of the Hennepin County Medical Society in the Medical Arts Building on Thursday evening, December 4, 1930, at 8 o'clock.

The meeting was called to order by the vice president, Dr. Theodore Sweetser, in the absence of the president. There were twenty-eight members and three visitors present.

Minutes of the November meeting were omitted on account of the length of the program of the evening.

The scientific program was at once taken up and consisted of the following:

Dr. Verne S. Cabot reported two cases as follows:

1. A Case of Splenomegaly with Anemia Complicated by Pregnancy. The patient was a young woman twenty-nine years old whose history prior to her twenty-third year was essentially normal. She was married at twenty-three years of age. The same year she submitted to an appendectomy. At twenty-four years she had a severe facial erysipelas which left her without apparent sequelæ.

During her first pregnancy, in her twenty-fifth year, she became very weak and pale. At this time she was suffering with a right-sided pyelitis, and because of this and her poor general condition she was sent to the hospital in her sixth month of gestation. Her pyelitis cleared up promptly. Early in her hospital stay she was found to have an enlarged spleen and liver, together with a marked anemia. She remained in the hospital because of her marked weakness and gastrointestinal upsets until her seventh month of gestation, when she developed a pneumonia during which she became jaundiced, causing a termination of her pregnancy at seven and one-half months.

Her hospital stay totaled twenty-six weeks. The jaundice persisted for two months, at which time she was discharged from the hospital at her insistence. She was told that despite the disappearance of her jaundice she was still anemic and that there had been little, if any, change in her splenic and hepatic enlargements.

Her condition for the next year and a half was one of improvement. There was no recurrence of her jaundice and she was told that her anemia was improving, though she still had a large spleen with a palpable liver. At this time she became pregnant, with a recurrence of her previous symptoms, terminating in an inevitable abortion at three months. There was no jaundice during this second pregnancy. Her convalescence was very slow, several months elapsing before she was up and about.

This young woman came under our observation at this time (1928). She was then in her twenty-seventh year. She was apparently suffering a recurrence of her previous symptoms, namely, prostrating weakness, gastro-intestinal upsets associated with loss of color. She told us that her present exacerbation of symptoms appeared three months previous, and that she attributed this recurrence to a third pregnancy likewise of three months' duration.

Examination revealed the patient to be a pale, listless individual, slightly jaundiced, and with evidence of recent weight loss. She stated that she had lost 23 pounds in the last three months. Physical examination revealed an upper-left-quadrant abdominal mass, probably spleen, extending downward to the level of the umbilicus and medially to the midline. The splenic notch was palpable. The liver margin was a finger's breadth below the right costal margin. There was no demonstrable ascites. There was a uterine enlargement suggestive of a three months' gestation.

Roentgen studies revealed no abnormality of the chest. *X*-ray studies of the abdominal viscera visualized a large mass in the upper left quadrant. No biliary calculi were seen. Her barium motor meals were essentially normal except for displacement of viscera by the splenic mass.

Her temperature readings were practically normal at all times. Laboratory findings, in brief, were: urine normal, contains no bile; Hb. 55 per cent, r.b.c. 4,430,000, w.b.c. 4,800. Differential cell counts were essentially normal. Blood smears were apparently normal beyond a slight tendency toward vacuolization. The clotting time was 4.25 minutes. Fragility tests showed initial hemolysis at .44 and complete at .33. The blood Wassermann was negative.

In view of the findings a diagnosis of splenomegaly with anemia complicated by pregnancy was rendered, and, in consideration of her previous experiences, removal of her spleen was recommended.

Laparotomy was done in June, 1928. A large spleen was found filling the left diaphragmatic dome and extending downward to the umbilical level and medially to near the midline. The liver was only slightly enlarged, with very little evidence macroscopically of gross changes. The gallbladder was large, grayish in color and thick-walled, with no palpable calculi in the biliary tract. A splenectomy and cholecystectomy were done.

Her postoperative convalescence was uneventful. She was discharged from the hospital on her fourteenth postoperative day. The pathologist reported a large spleen retaining its original shape, sections of which showed a diffuse hyperplasia with fibrosis of both pulp and corpuscles. Histologically it was a splenomegaly of the Banti type. The gallbladder showed a much thickened wall. Diagnosis: chronic cholecystitis.

As to her subsequent history, her pregnancy was uninterrupted, going to full term, and she was delivered of a viable child which, to date, is apparently normal. We have watched her progress relatively close. She is without complaint, her weight is back to normal and she is able to do her housework. Recent laboratory studies show a normal urine, the hemoglobin averages 75 per cent, cellular counts are within normal ranges, as is the fragility test.

There is no history obtainable of similar afflictions in her family tree. (The patient was presented before the Society.)

2. A Case of Hemolytic Icterus Complicated by Extensive Healed X-ray Burns Over the Splenic Area.

This patient was first seen by Dr. Cabot in 1926, at which time she was twenty-four years of age and unmarried. Her history revealed that she had been jaundiced from birth; the jaundice varied as to degree of intensity, but at no time was she entirely free. Associated with her jaundice was extreme lassitude, at times so severe as to completely invalid her. She had been under medical supervision since birth, being treated principally for her anemia, the medication including extensive and repeated hospitalization periods, at which times she received numerous blood transfusions. There was no history in her family tree of others similarly afflicted.

Early in her childhood a mass was palpable in the upper left abdominal quadrant. This mass had gradually grown in size to date. The predominant symptoms throughout had been weakness, pallor, and a persistent jaundice. At the age of eighteen she first noticed a chain of gastrointestinal symptoms consisting of abdominal bloating, aversion to fat, increased constipation, and symptoms suggestive of gallstone colic associated with dark urine and clay colored stools.

At the age of twenty-two she suffered a third degree *x*-ray burn over the region of the spleen and the lower portion of the left breast. This was the result of improper roentgen therapy for her apparent splenomegaly. She stated that she had received but one massive treatment, the burn showing up on the sixth day following. It was at this time that she came under Dr. Cabot's observation seeking relief primarily from this extensive *x*-ray burn. She was immediately hospitalized, receiving repeated blood transfusions in addition to local treatment for the burn. Fourteen months elapsed before the burned area was completely healed. Following this the patient presented herself for relief from her abdominal discomfort and persistent jaundice. The icterus was severe enough to cause intense itching.

The physical examination was essentially normal beyond the abdominal findings, consisting of a massive healed scarred area over the upper left abdominal quadrant and a smaller area involving the lowest pendulous portion of the left breast. There was a large intra-abdominal mass in the upper left abdominal quadrant, the upper portion of which could not be made out. At various examinations the lower pole extended to the upper border of the left iliac crest and medially to the midline. The splenic notch could not be demonstrated. The mass was apparently fixed.

Roentgen studies of her chest revealed no abnormalities. Gastro-intestinal studies revealed a lamellar calculus in the gallbladder and the presence of a large mass in the splenic area. The findings from the numerous motor meals were normal beyond a displacement due to the large splenic tumor. Her hemoglobin averaged 50 per cent, ranging from 15 to 55 per cent; r.b.c. 4,000,000, w.b.c. 6,000. Differential count was normal. Blood smears showed many microcytes and some pessary forms. The clotting time was 3.5 minutes. The blood Wassermann was negative. The fragility test showed hemolysis starting at .49 and complete at .41. Urinalyses were normal except for the presence of bile, which was found at repeated examinations. Gastric analyses showed free acid within normal ranges.

The problem of surgical relief in this patient was complicated by the presence of this extensive scarring from the *x*-ray burn, with unknown involvement of the underlying tissues. The question arose as to the degree of fixation resultant from the overly-intensive roentgen therapy. In addition, the presence of biliary calculi, which were causing severe gastro-intestinal upsets, further complicated the picture. It was the preoperative opinion of both Drs. Bell and O'Brien that the splenic condition was of greater importance and should be dealt with first; also, that the apparent fixation of the mass was probably little influenced by the severe radiation. This was borne out at the operating table.

The patient submitted to operation in November, 1927, at which time an enormous spleen was found filling the upper left abdominal quadrant and extending downward to the upper border of the left iliac crest and medially to the midline. There were numerous relatively fine adhesions between the spleen and the left diaphragm. Whether or not these were the result of the intensive radiation is conjectural. The liver was slightly enlarged with rounded edges. The gallbladder was thick-walled, containing one large calculus which had been visualized preoperatively, and numerous smaller calculi. A splenectomy and cholecystectomy were done, at the termination of which a direct blood transfusion was given.

The postoperative convalescence was uneventful. By the fifth day the jaundice had disappeared for the first time in her life. The wound healing was apparently normal. She was discharged from the hospital on the nineteenth postoperative day.

The Department of Pathology at the University reported a spleen of approximately 2,800 grams, showing very marked pulp congestion with extremely small and relatively infrequent sinuses. This is probably the most typical histologic picture in congenital hemolytic jaundice. Sections of this spleen were shown by Dr. Cecil J. Watson at a subsequent meeting of the Pathological Society at which the histologic changes in this disease were discussed.

Three years have now elapsed since the operative procedures above described. The young lady has enjoyed apparently normal health to date. Recent laboratory studies show a bile-free urine, hemoglobin of 80 to 85 per cent, and cellular studies of the blood are apparently normal. Her fragility tests are still slightly increased, hemolysis starting at .44 and being completed at .42.

(The patient was presented before the Society.)

DISCUSSION

Dr. E. A. Regnier asked as to the condition of the liver in the first case.

Dr. Cabot said there were not many changes and microscopically there was very little change. The liver was palpable. Neither of these patients had ascitic fluid.

Dr. Ivar Sivertsen said he wished to compliment Dr. Cabot on these cases and reporting them to the Society. The question of the spleen has always been of interest, having been recognized by the ancients, even as far back as Aristotle, who had noticed that the spleen might be congenitally absent; and a sect of surgeons in 1700 made quite a reputation for themselves by removing the spleen. It was in 1885 that Drs. Simon and Haeckle of Darmstadt, Germany, were especially interested in the question of the spleen and splenectomy and at that time it was argued that there was no reason for the removal of the spleen, and the Surgical Society of Hesse decided it should be done only for injury. Collier, in 1882, compiled studies of the spleen and concluded that the operation of splenectomy could be justified in cases of splenoptosis, cysts and idiopathic enlargements of the spleen. Mayo and others have worked on the spleen and have found that it could be removed for splenic anemia, hemolytic jaundice, Gaucher's disease, and selected types of early pernicious anemia.

Dr. Sivertsen thought this case of Dr. Cabot's was probably one of splenic anemia so that it came within the range of removal. He said the question of operative procedure had always interested him and he noted that Dr. Cabot had used the median incision. Dr. Sivertsen believed that making a transverse incision, cutting across the left rectus muscle and going over to the right rectus muscle, greatly facilitated the removal of the spleen. He said it was very important that adhesions be clamped and tied before liberation of the spleen was attempted, after having first ligated the splenophrenic ligament. Then the question of dealing with the pedicle of the spleen was also of interest to Dr. Sivertsen. It is very friable and must not be handled roughly for it has happened that the spleen has been torn away in this way. Dr. Sivertsen said there was one thing Dr. Cabot had not brought out and which he felt was worth while, and that was hemorrhage following splenectomy; and that one might still have a very severe hemorrhage from some of the mucous membranes of the body after such an operation, even after a few hours or as long as seven years after.

Dr. Sivertsen wished to thank Dr. Cabot again for bringing these cases before the Society.

Dr. Rishmiller asked as to where these hemorrhages might occur.

Dr. Sivertsen said they might come from the mouth, uterus, or any of the mucous membranes.

Dr. Theodore Sweetser remarked that it might be encouraging to recall the case of severe third degree Banti's disease with ascites reported by Dr. H. B. Sweetser, Sr., in 1920. Clinically the patient has remained well, according to their latest word, even quite recently, though the blood picture has never become entirely normal. A splenectomy, even when done late, may effect a clinical cure.

Dr. Thomas J. Kinsella reported a case of Retrograde Intussusception of the Jejunum through a Gastroenterostomy Stoma observed on the Surgical Service at Glen Lake Sanatorium in September, 1930.

The patient, a woman forty years of age, suffering from an advanced pulmonary tuberculosis, had apparently carried the condition and been totally obstructed for three days before the surgical consultation. The posterior gastrojejunostomy through which the intussusception occurred had been done some five years previously for a duodenal ulcer and apparently had functioned perfectly until this complication arose. At operation the stomach was found filled with the intussuscepted jejunum, which was gangrenous and irreducible. Resection was not attempted because of the patient's critical condition. Death occurred twenty-four hours later.

The complete specimen obtained at postmortem was presented.

The case report, which included a review of the twenty-seven somewhat similar cases collected from the literature, was illustrated by a series of lantern slides showing the various types of conditions encountered.

DISCUSSION

Dr. Verne S. Cabot said he wished to compliment Dr. Kinsella upon this detailed report of so interesting a case. The essayist had called attention to the difficulties of accurate preoperative diagnosis, as these patients are usually seen late in their acute phase of the obstruction.

Dr. Cabot said he wished to report a similar case that had come under their care in 1926. The patient, a young man of twenty-six years of age with a history of duodenal ulcer, had submitted to a transmesocolic gastrojejunostomy in 1922 at an Army Hospital. He was much improved for several years following the operation, when he began again to have indigestion with upper abdominal discomfort, terminating in obstruction similar to the case just described by Dr. Kinsella.

They first saw this patient seventy-two hours after the onset of symptoms, at which time he was lying in the hospital in a semi-comatose condition with a markedly distended abdomen. From relatives they had learned the above history. He was markedly dehydrated and was vomiting periodically, the emesis appearing fecal in character. He was given forced fluids by all avenues, as well as repeated gastric lavage, and a few hours later a laparotomy was done at which a complete obstruction of the gastrojejunal stoma was found due to the angulation and intussusception of the distal arm of the transmesocolic gastrojejunostomy anastomosis into the stoma. The reverse peristalsis in the distal arm emptied contents into the stomach, but none could pass outward due to the trap effect of the intussusception of the jejunum through the stoma. The proximal arm of anastomosis was 5 inches in diameter and markedly indurated due to continued pressure and irritation. Fortunately the intussusception was reducible. An entero-anastomosis of the afferent and efferent loops was done. In addition, the efferent loop immediately adjacent to the stoma was lightly stitched to the gastric wall to further prevent a recurrence of the intussusception.

The patient's postoperative period was very stormy for the first few days, during which he suffered a double parotitis. He was discharged from the hospital on his twenty-first postoperative day. They had watched this young man to date and at intervals had subjected him to gastro-intestinal examinations which show normal functioning of short-circuiting mechanism. He has remained symptom-free.

In the absence of Dr. A. L. Herman, who was to have read his thesis at this meeting, an informal discussion was held on gunshot wounds of the abdomen and the following cases were reported:

1. Dr. R. R. Cranmer reported the case of the bandit recently shot in a restaurant holdup, who received five bullet wounds. One penetrated the scalp without entering the skull, and two passed through the left arm. There was another gunshot wound in the lower left quadrant which penetrated the small bowel three times. The bullet penetrated the mesentery of the sigmoid and lodged in the left iliac fossa. It must have penetrated the bowel on both sides at one point and then just grazed the wall at another point, as there were only three holes. These three holes were all within a distance of two inches of each other. Then he had another one which entered just below the spleen on the left side and took an upward course into the left chest, evidently not hitting any blood vessels. He has not vomited blood and there has been no blood in the urine, but at operation he had quite a lot of blood in the peritoneal cavity. At operation three cigarette drains were inserted through the incision, also another drain through the opening where the second bullet entered the abdomen.

Dr. Cranmer stated that so far the patient had been getting along all right; in fact, better than it was first thought he would.

2. Dr. Theodore Sweetser remembered two peculiar bullet wounds. The first was in a negro who was admitted to the Minneapolis General Hospital after having been shot in the left hip. Roentgenogram showed the bullet in the pelvis to the right of the midline, but before it could be further localized he voided a large quantity of bloody urine, and with it the bullet. Operation showed that the bullet, without entering the peritoneal cavity, had torn off the lower end of the left ureter, entered the bladder just medial to the left ureteral orifice, penetrated the right wall of the bladder farther forward, and finally had fallen back into the bladder and been voided with the urine.

The second case was seen at autopsy at a base hospital in France during the war. The man had been shot in the right flank. During operation for extraction of the bullet, the bullet had disappeared. From the noises heard over the precordium, it was evident that the bullet had been dislodged into the hepatic vein and had found its way to the heart. After apparently doing well for a week or ten days, the man suffered an evident pulmonary embolism and the noises over the precordium ceased. When he was apparently recovering from his injuries, he acquired diphtheria from another patient and died from the diphtheria. At autopsy a recent pulmonary infarct was found, with the bullet plugging the corresponding fairly large branch of the pulmonary artery.

3. Dr. R. F. McGandy reported the case of a girl who had shot herself on account of a love affair. The bullet, 32 caliber, entered her abdomen in the midline just below the xiphoid process and in its course through the abdomen penetrated the left lobe of the liver, the stomach and the left kidney. The patient was transfused immediately upon her arrival at the hospital. She was given a general anesthetic, after which clear blood was removed from the bladder by means of a catheter. An upper left rectus incision was made. The outer third of the left lobe of the liver was practically amputated by the injury. The liver defect was repaired. The stomach, both front and back, was closed in the usual manner. A large amount of free blood was found, not only in the abdominal cavity but also in the lesser peritoneal cavity. Because of the patient's condition nothing was done to the kidney at this time.

The significant thing in this case was the large number of complications following this gunshot wound. The patient first developed a pneumonia, which resolved in due time, leaving a pleurisy with a small amount of fluid in the left chest. On the tenth day she developed a marked adenitis on the left side of her neck which subsided upon the application of cold packs. Shortly following this she had a severe diarrhea, having ten to twelve stools for two days. This was closely followed by a pyelitis. She was discharged from the hospital seven weeks following the operation.

The meeting adjourned.

H. O. McPheeters, M.D., *Secretary.*

THE FRANK W. FRIEND FRAUD

Under the trade name "Frank W. Friend," Mrs. N. F. Lockwood of Littleton, Colorado, has been selling through the mails a so-called Wonder Remedy for Men. The alleged wonder was composed largely of extract of saw palmetto berries and, according to the postal official's report, was obtained from Parke, Davis and Co. Mrs. Lockwood started the business about November, 1928. She claims to have had the assistance of her brother, Frank L. Palmer, who has been associated with similar ventures, in preparing the advertising matter. According to the postoffice authorities Mrs. Lockwood got two dollars a box for one hundred pills which cost her seven and a half cents from Parke, Davis and Co. On June 30 the Postmaster General debarred the Frank W. Friend fraud from the mails. (Jour. A. M. A., July 26, 1930, p. 285.)

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

EYE, EAR, NOSE AND THROAT

MANAGEMENT OF OTITIS MEDIA IN CHILDREN: Dr. Edmund Prince Fowler (The Laryngoscope, Vol. XL, October, 1930). This article is certainly a very sound and comprehensive view of the subject title. The author first states that, after all, the removal of the cause is the best treatment of disease (an old and time-worn axiom, but nevertheless one frequently temporarily forgotten). He divides his approach to the problem into four subdivisions: 1. Elevation and cure of the infection. 2. Prevention of complications. 3. Restoration and preservation of the hearing. 4. Prophylaxis for the opposite ear and for recurrence of the inflammation.

These objectives are all obtained by adequate drainage through the eustachian tube, and spontaneous rupture of the drum or its incision. Simple mastoidectomy is the conservative procedure when the child still shows or begins to show increasing signs of sepsis or complications. Non-suppurative and suppurative otitis media often occur in children without pain or manifest distress or discharge. The most perfectly treated ear infections may go on to mastoiditis, sinus thrombosis, and meningitis, and the most negligent speedily recover with perfect hearing. The author severely condemns too much operating by otolaryngologists in the early stages with subsequent reactions. The tendency of the otolaryngologists is to exaggerate the danger of middle ear disease and mastoiditis and to rush patients into operations. Excluding trauma, abscess in the ear has its etiology in the naso-pharyngeal spaces. The ear is but one of the nasal sinuses and should be so treated. Failure to conquer the disease in the naso-pharyngeal spaces is the outstanding crime in otological practice today.

Treatment of the nose and its sinuses is of prime importance in the obtaining of the four main objectives outlined. The author demonstrates by roentgenogram that 86 per cent of his cases of transitory, chronic, or progressive deafness are intimately associated with disease of the sinuses.

Experimental work has given considerable evidence that deficiency in Vitamins A and D and calcium phosphorus imbalance are associated with middle ear and sinus infections. These factors were given careful study in all of the author's cases. Each patient received in addition to a careful otologic examination, audiometer tests, stereoscopic roentgenograms, blood chemistry, Wassermann, and intercutaneous T. B. tests; also careful inquiry into nutritional disorders and the diseases of childhood.

L. C. C.

IMPORTANT POINTS IN TONSILLECTOMY: A. M. Painter, Kansas City, Mo. (Annals of Otol., Rhinol. and Laryngol., Vol. XXXIX, Sept. 3, 1930). This worthwhile article is mainly a strong plea for *complete* removal of tonsil and *capsule;* together with a description of technic which would seem to be "foolproof."

Attention is called to the high percentage of tonsillar remnants remaining after tonsillectomy. Invariably, these are infected and sealed in. The patient is therefore in a more dangerous condition from the angle of "focal infection" than before operation. These results (73 per cent) are usually due to unremoved bits of tonsil (and, or) capsule, which have the power of reproduction to an amazing degree.

A clear description of the tonsillar capsule and pharyngeal aponeurosis is then given, with especial reference to the plica triangularis. This latter should be considered as a part of the capsule (not of the anterior pillar), and its complete removal is imperative to insure a throat free from infected tissue, and a decent cosmetic result.

An unobstructed view must be had throughout the operation; the sense of touch cannot be depended upon.

Anesthesia is important, and a clear description of the author's given. Particular attention is given to dissection along the post-pillar (a step usually omitted by many surgeons). Incisions are made through the mucosa with a very sharp knife to avoid tearing the membrane. The incision along the anterior border of the anterior pillar is very important, as it should entirely free the plica triangularis from the anterior pillar, leaving it attached to the tonsil. The anterior and posterior incisions are joined above the tonsil by severing the mucous membrane between their upper extremeties. Dissection is started from below upward, where tongue and anterior pillar join, line of cleavage located, and dissection continued backward and upward. Vessels are clamped before being cut. The upper pole is freed and dissection carried down the posterior pillar to the base. Usually the gland is completely freed by dissection, but often a snare is used at the base or "root" of the tonsil.

M. W. Wheeler, M.D.

BRAIN ABSCESS AND METHODS OF DRAINAGE: Henry P. Cahill (Trans. Amer. Acad. of Oph. and Oto., 1929, Page 96). In abscess of the temporo-sphenoidal lobe the approach must be made either by a bone flap, a temporo-parietal decompression, a subtemporal decompression or through the mastoid tegmen. The bone flap approach gives a large field and theoretically has the advantage, but practically in the hands of the otologist this is not so. The subtemporal decompression is valuable in moribund cases with a sclerotic mastoid.

The approach through the mastoid has given a higher average of recoveries than any other method. Here the granulations on the dura or the exposed dura are a guide to the meningeal or intra-cerebral abscess in over fifty per cent of cases. Here the abscess is frequently near the cortex and at times opens to it by a fistulous tract. The cortical cells do not belong to any important cerebral center in this area. The ideal treatment would be to remove the abscess, in toto, but there are several insurmountable obstacles in the way of its success. In frontal and temporo-sphenoidal abscess, especially if it is on the right side, the King technic must be given ample consideration.

The other methods vary from complete evacuation and inspection of the lining capsule with the encephaloscope, to simple repeated punctures. The removal of a cone of cerebral tissue reaching to the capsular wall has proved very satisfactory, using the large drainage tube. The drain when in proper position should not be disturbed for from four to six weeks; after this time the stay sutures may be removed and the brain allowed gradually to expel the drain. Lipiodol injection is indicated in all drainage cases with persistent purulent discharge, headaches or any questionable symptoms, since the tube may be outside the capsular wall. The para-mastoid route, through Trautman's triangle, with at times obliteration of the lateral sinus, is the way of choice in cerebellar abscesses in which the symptoms or signs of labyrinthine involvement preceded those of cerebellar infection. If the abscess is secondary to sinus involvement, drainage through the inner sinus wall is preferred.

L. G. Flanagan, M.D.

GYNECOLOGY AND OBSTETRICS

THE HYDROGEN-ION CONCENTRATION OF THE BLOOD IN ECLAMPSIA: H. J. Stander, M.D., and N. J. Eastman, M.D., Baltimore, Md. (Amer. Jour. Obst. and Gynec., Vol. XX, No. 6). A report of the findings in a study of eight additional cases of eclampsia further strengthened their belief that eclampsia at the time of convulsions is associated with a true acidosis, due to an uncompensated alkali deficit, as is demonstrated by a definite increase in the hydrogen-ion concentration. Also, they believe that the acidosis probably should not be regarded as a causal factor, but rather as the result of the eclamptic convulsion, and by itself is sometimes severe enough to cause death.

The increase in the hydrogen-ion concentration of the blood immediately following an eclamptic convulsion often reaches the level of a true acidosis, and the eclamptic patient usually overcomes this by lowering the carbonic acid through deep breathing, resulting in transitory periods of acidosis following convulsions. If, however, the patient is unable to overcome the acidosis, death may ensue unless proper anti-acidosis treatment be given. They recommend following the CO_2 combining power of the blood as an index of the acid-base equilibrium.

Russell J. Moe, M.D.

AN ANALYSIS OF FIFTY CASES OF TOXEMIA OF PREGNANCY: P. D'Acierno, M.D. (Amer, Jour. Obst. & Gynec., Vol. XX, No. 6). An analysis of fifty cases of toxemia of pregnancy following Stander's classification with the number of cases in each group:

		Number of cases
I	Eclampsia	21
II	Pre-eclampsia	8
III	Low Reserve Kidney	8
IV	Chronic Nephritis Complicating Pregnancy	8
V	Hyperemesis Gravidarum	5

There were no cases of acute yellow atrophy or impetigo herpetiformis.

In the eclamptic group 62 per cent were primiparæ as against 38 per cent multiparæ. The higher percentage of primiparity in eclampsia is, in his opinion, due to the fact that in the first pregnancy the different body-systems fail to adequately adapt themselves to the demands of the fetal parasite, and respond with an exaggerated abnormal reaction, which resolves itself into the eclamptic attack; in multiparæ there appears to be in action a better mechanism of adaptation between the mother and fetus, as though a sort of relative immunity had been acquired in a previous pregnancy. Acute infectious disease was common in the first four groups and may be considered as an important factor in the production of renal and hepatic impairment.

The "low reserve kidney" (Stander) is one which, handicapped by some cause, either congenital or acquired, is unable to function at full capacity under the stress and strain of pregnancy.

The carbon dioxide combining power was found to be definitely decreased in eclampsia, pre-eclampsia and chronic nephritis. He believes this finding to be a good index of prognosis. The blood sugar values were increased in all groups except hyperemesis gravidarum.

Increased blood pressure was found in all groups except hyperemesis, where instead there was hypotension.

Maternal mortality was 8 per cent; the fetal mortality 25.5 per cent, or, deducting stillbirths, the corrected fetal mortality was 21.5 per cent.

Russell J. Moe, M.D.

CONCERNING SPASMODIC CONDITIONS OF THE UTERUS AND TREATMENT: P. Burger (Gynecologie et Obstetrique, Tome XXII, No. 1). The author considers a rather vaguely defined condition which is characterized by short ineffectual uterine contractions which become extremely painful and cause long delay during the second stage of labor. These vary greatly both in frequency and intensity and contribute nothing to the progress of labor, but are most exhausting to the patient. Walthard gives four types: clonic contractions, tetany of the uterus, stricture of the uterus with spasm of the internal os, and trismus or spasm of the external os. The author recognizes three types of uterine contraction: (1) normal, (2) hypotonic or weak contractions, and (3) exaggerated hypertonic contractions with insufficient relaxation intervening. Clinical differentiation is difficult.

The cause is usually associated with relative obstruction or interference, resulting in hyper-excitability of the sympathetic nervous system, similar to that seen in spasmodic constipation or certain forms of ileus. The obstruction may be due to fetal or pelvic dystocia, and to conditions of the uterus itself. He considers only the latter factor. Slow effacement of the cervix with painful spasm may be due to constitutional factors, sometimes familial, which is relatively rare, scar tissue in the cervix resulting from lacerations or infection from gonorrhoea or previous instrumentation.

Interference with normal uterine function by presence of large amount of amniotic fluid. Recognition of the condition of hypertonus is most important as it must be overcome before labor can progress.

Concerning treatment, the author suggests: The use of hypnotics or narcotics hypodermically or by rectum; early rupture of membranes, incisions of the cervix, or, in case of dense scar and spasm, vaginal or abdominal hysterotomy.

A. L. McDonald, M.D., F.A.C.S.

THE INCIDENCE OF PUERPERAL INFECTION DUE TO ANAËROBIC STREPTOCOCCI. T. K. Brown (Amer. Jour. Obstet. and Gynec., Vol. XX, No. 3). The author brings out the importance of anaërobic organisms, especially streptococci, as a cause of puerperal infection. He reviews the studies of Schottmuller, Harris, Brown and others. This is a continuation of studies made in conjunction with Schwarz and Dieckman in St. Louis. A large percentage of their cases of infection were due to anaërobic non-hemolytic streptococci not shown in ordinary blood cultures. They believe that these organisms enter the body from the vagina. As a prophylactic measure they have been using a vaginal instillation as suggested by Bessesen, during labor:

Mercurochrome crystals, 15.
Tctr. iodin one-half strength, 5 c.c.
Glycerine, 500 c.c.

This is used to destroy the anaërobes present in the vagina and is repeated every twelve hours during labor or following premature rupture of the membranes. Since this routine was established three years ago the morbidity and mortality from puerperal sepsis has been reduced more than one-half.

A. L. McDonald, M.D., F.A.C.S.

FIBROMYOMATA UTERI, TREATMENT AND END-RESULTS: Keene and Kimborough (Amer. Jour. Obstet. and Gynec., Vol. XX, No. 2). Here is presented a valuable study concerning indications, methods, and results, based on many years experience and careful observation. The report includes 245 consecutive cases which required treatment because of the following symptoms: menorrhagia, 62 per cent; metrorrhagia, 9 per cent; lumbo-sacral pain, 27 per cent; pressure symptoms, 29 per cent.

Radium is chosen for women in the fifth decade with tumors smaller than three months pregnant uterus, where bleeding is the only symptom. They accept as contra-indications to radium:

1. Tumors larger than a three months pregnancy because of frequency of degeneration, and disease of the adnexa, also distortion of the uterine cavity which interferes with a satisfactory curettage.
2. Recent rapid increase in size of the tumor.
3. Presence of pressure symptoms.
4. Tumors associated with pelvic pain because of frequency of tubal or ovarian lesions.
5. Pedunculated tumors.
6. Profound anemia out of proportion to loss of blood, as this may indicate degeneration of the tumor.
7. Uncertain diagnosis, and never without diagnostic curettage.
8. Stenosis of the cervical canal.
9. Tumors in young women or those who are unduly nervous.

The authors find that from year to year a larger per cent are selected for surgery, largely from more rigid adherence to contra-indications for radium. In this series 21.4 per cent were treated with radium. The dosage has been decreased to from 600 to 900 milligram hours, to be followed by *x*-ray if necessary.

X-ray was selected in 4.7 per cent where the tumors were complicated by adnexal disease or who were poor operative risks because of profound anemia, or in the presence of large tumors in patients where surgery was contra-indicated.

Surgical treatment was offered in 180 cases or 73 per cent; vaginal myomectomy in 3.3 per cent; abdominal myomectomy in 6.4 per cent.

Hysterectomy was usually selected, conserving at least one ovary in situ whenever possible. They prefer subtotal hysterectomy, believing that with proper treatment of the cervix the risk of subsequent cancer is much less than the added risk of total hysterectomy.

A. L. McDonald, M.D., F.A.C.S.

MEDICINE

EPITUBERCULOSIS: B. Goldberg and B. M. Basal (Amer. Jour. Med. Sci., December, 1930, 824-832). Massive areas of pulmonary infiltration in children having positive tuberculin reaction were formerly considered of grave prognosis.

Eliasberg and Neuland in 1920 found this conception erroneous, demonstrating cases with subacute onset and course, extensive physical signs, heavy, dense, well demarcated *x*-ray findings, with gradual disappearance of both signs and shadows in a few weeks or months, with exception of enlarged hilus glands and the positive skin reaction.

They differentiated the condition from caseous tuberculous pneumonias, and from chronic non-tuberculous pneumonias, chiefly by the history of acute onset in each case, and the presence of lower lobe involvement.

They note in epituberculosis the presence of nonspecific involvement on specific tuberculous soil.

The condition had been earlier described by Grancher, Bourdel, Hutinel, Sluka, Ranke, Tendeloo, Frankel, Ribadeau, Dumas, Gravinhoff, Engel, Epstein, Gohn, Langer and others, under the terms splenopneumonia, para- and perituberculosis and epituberculosis. Goldberg and Gasul report ten cases with roentgenograph study, one of which indicated a re-infiltration of the entire right lung following a tuberculin test. They conclude with a summary of these cases, showing that epituberculous infiltrate is intimately associated with the reactions of the tubercle bacillus or its toxins, and are uncertain whether the epituberculous area is a collateral inflammation, or an atelectasis due to blockage from hilum pressure, or a truly parenchymal involvement. The bibliography is complete.

J. G. Lamont, M.D.

SOME PROBLEMS IN THE DIAGNOSIS AND TREATMENT OF THYROTOXICOSIS: Fred E. Ball, Chicago, Ill. (Am. Jour. Med. Sc., Nov., 1930). Thyrotoxicosis presents many problems which at times cause great difficulty in diagnosis or treatment. The basal metabolism has always been considered of great value in the diagnosis of thyrotoxicosis, but the author wishes to call attention to a group with only slightly elevated rates. In contrast, several cases have been observed with typical symptoms of thyrotoxicosis but with a normal rate. However, this rate tends to become elevated later on without any particular change in the symptoms.

Summarized, the author believes that the symptoms of thyrotoxicosis may be present preceding a rise in the basal metabolism. Too much attention should not be given to one normal reading when the clinical picture suggests a thyrotoxicosis.

Hypometabolism and myxedema are two different things and should not be confused. There is a group of cases which following thyroidectomy develop myxedema and which cannot be returned to normal by thyroid medication.

A recurrent thyrotoxicosis may exist where no thyroid tissue can be demonstrated.

The relationship of pregnancy and thyrotoxicosis is associated in a sufficient number of cases to bear careful study, and the connection between them, if any, is not at the present time clear.

RICHARD BARDON, M.D.

THE ADRENALIN TEST AND CHOLESTEROL DETERMINATION IN THE DIAGNOSIS OF BORDERLINE HYPERTHYROID: J. William Hinton (Amer. Jour. of the Med. Sci., Nov., 1930). The author has made use of the adrenalin test as advocated by Goetsch, and in addition a determination of the leukocyte and differential counts taken before the injection, and at 15, 45 and 90 minute intervals after the injection. This addition was recommended by Goetsch in 1929.

In the positive cases of hyperthyroidism definite uekocytosis is produced after the injection.

In addition, complete blood chemistry studies, with particular reference to the cholesterol findings, were also included. He felt that there might be a disturbance in the cholesterol metabolism.

All in all, observations were made in twenty-six cases, and they came to the conclusion that as an aid in the diagnosis of borderline hyperthyroidism, the adrenalin test, with the leukocyte and differential counts added, has not been of any assistance in making the diagnosis.

There were no typical findings as far as the cho-esterol content of the blood was concerned.

He came to the conclusion that the test seemed to be so delicate that any patient with a thyroid enlargement will give a positive reaction unless a definite hypo-hyroidism is present.

RICHARD BARDON, M.D.

SURGERY

THE TREATMENT OF HARELIP AND OTHER FACIAL CLEFTS: Prof. Dr. Fritz F. Hartel, First Surgical University Clinic at Osaka, Japan (Der Chirurg, Vol. II, No. 23, December 1, 1930). The author reviews recent advances in the treatment of harelip, and adds thereto his technic of operation, lay-ng stress on the fundamental principles involved, the attention to which will bring about a good cosmetic and functional result. He reviews the more recent work of authors in the development of this operation, and mentions especially:

Escher, who, in 1920, described the double row suture; Drachter described the simple angular refreshing of he vermilion borders; Ramstedt, in 1922, described the manual replacement of the premaxilla; H. Meyer, in 926, described the building up of the upper lip in three ayers, and the reconstruction of the nasal floor; H. Ehrenfeld, in 1926, described the reconstruction in con-inuity of the lip musculature with a three-row suture; A. Hagendorn, in 1923, described the plastic of the nares; V. P. Blair, in 1928, described his method of mensuration, and careful correction of nasal deformity, and of the curve of the lips; F. Hartel, in 1929, described reconstruction of the ideal center of the lip, muscle, suture, and mensuration.

These references give, as the author's background, the more recent developments in this work, as they appear in the German literature. In carrying out his present technic, Hartel lays down the following fundamental facts:

1. All tissues are present; the cleft denotes no division, but a separation of continuity; the parts have spread away from each other, the muscles retracted, the skin piled up, and has rolled in. It is as if an earthquake had thrown apart the building stones of the upper lip; if we can set each stone again in its proper place, the structure will be complete, and the natural architecture will remain.

2. The most important component of a building is not the façade, but the supporting structures; if these are missing or do not function properly, then one cannot cover these defects with superficial structures only, and expect good cosmetic or functional results; the supporting structure, in this instance, is the musculature. Thus, the fundamental object to be obtained is the reconstruction of the concentric muscular ring of the mouth and nose.

3. By the deft exposure and suture of the pliable muscle layer, it is surprising how easily one can get a good skin and vermilion border suture. All tension is gone, making it unnecessary to use complicated sutures, and naturally one attains a nicer cosmetic result. One cannot retain the proper relations unless one uses a compass and millimeter rule, and one does not tie sutures until all measurements coincide.

The author then describes in detail the carrying out of these principles as they are practiced, and have proven quite successful in his hands.

The author also applies these principles to the repair of defects in the oral cleft, due to disease or injury.

While nothing distinctly new is offered to the man conversant with the development of harelip surgery, yet to him, especially, the reading of this article completely, will well repay the effort.

A. E. SOHMER, M.D.

THE SURGERY OF DIABETES AS IT CONCERNS GANGRENE OF THE LOWER EXTREMITIES AND CARBUNCLES: Urban Maes, M.D., (Surg., Gynec. & Obstet., Nov., 1930, p. 700). Insulin has reduced operative mortality from 50 per cent to a range between 2 to 10 per cent. The number of diabetics is steadily increasing. Diabetics are susceptible to two particular surgical diseases: gangrene, chiefly of the lower extremities; and infection, chiefly in the form of carbuncles of the neck. Infection reduces the efficacy of insulin from 50 to 75 per cent.

In operating upon diabetics an extremely close cooperation between surgeon and internist is important, both before and after the operation. Diet and insulin therapy must be controlled with almost mathematical precision. Diabetics with infection must be treated before and after operation as if coma were impending.

Use of ether is contra-indicated because of its tendency to acidosis and hyperglycemia. Local anesthesia is contra-indicated because of local tissue injury resulting in great susceptibility to infection. Ethylene is most generally satisfactory, but, where contra-indicated, spinal anesthesia may be used.

Gangrene in diabetes is usually superimposed upon an already existing arteriosclerosis. The latter occurs earlier by 10 years (Eliason) than the usual arteriosclerosis. It is followed by infection or may follow infection and in the latter case is due to poor hygiene of the feet, wearing ill fitting shoes and hose, use of radical corn cures and the cutting of corns and calluses.

Operation for gangrene must be done early. Emergency operations are evidence of lack of co-operation between internist and surgeon somewhere along the line.

Heidenhain held that amputation should be done above the knee, because of better collateral circulation, resulting more likely in primary healing. However, it is known that the mortality rises the nearer the amputation is done toward the trunk and secondly an artificial limb can seldom be satisfactorily fitted above the knee, that is, leverage for manipulating the leg is lacking.

The author believes the chief reason for failure of primary healing below the knee is not defective blood supply but a too elaborate technic, namely beveling, flap formation and complicated dissection. These invite gangrene and infection.

The author amputates at the junction of the middle and upper third of the leg by the old method of Kocher, which was widely used in the war.

The skin is incised and allowed to retract. The muscles are cut at the level of the retracted skin. The bone is cut at the level of the retracted muscles. About four sutures are inserted into the deep aponeurosis drawing the tissues over the face of the stump. The same number are used to approximate the skin. No tourniquet is used. Vessels are ligated individually. Careful hemostasis is important. No drainage is used, because it invites infection.

The author had only two deaths in approximately sixty cases and these occurred in pre-insulin days. In the rest all but two cases resulted in primary union.

In the treatment of carbuncles of the neck the grid-iron incision is used exclusively. This consists of a series of parallel vertical incisions extending deep into the carbuncle and extending outward into the surrounding healthy tissue. Bleeding is controlled by gauze soaked in 1 per cent carbolic acid solution.

Harold J. Dvorak.

ACUTE PANCREATITIS, ABDOMINO-LUMBAR TRANSFIXION IN THE DRAINAGE OF ACUTE PANCREATITIS: F. Ody, Geneva, Switzerland (La Presse Medicale, No. 29, 1930, No. 96). The author describes the anatomy of the region of the pancreas, and mentions a method of drainage which he has found satisfactory in the treatment of acute pancreatitis; without going into the disputed etiology of this condition, taking it for granted that at the present stage of knowledge, early and thorough drainage is indicated, and that drainage through the anterior abdominal wall is not always satisfactory.

A method is mentioned by which both anterior and lumbar drainage is used in this condition. The technic is as follows:

Median anterior incision, going through the large omentum, exposing the superior border of the pancreas; a preliminary palpation of the gland, to determine its pathology, is made; the insertion of drains is made above the splenic artery, thus avoiding the superior pancreatic arterioles, and being careful not to wound the splenic veins. A left lumbar incision is then made, dissecting to the renal hilus; again looking for the splenic vein, avoiding this, bluntly breaking through the tissues until the pancreas is reached; drains are placed below or behind the same. This method of drainage is especially useful if necrosis is extensive in the caudal end of the pancreas. If necrosis is extensive in the head, then it might be practical to put anterior drains to the right of the duodenum, in addition to, or in place of, the sub-omental drains.

Two illustrations accompany the article.

PEDIATRICS

THE INFLUENCE OF FEEDING ON CERTAIN ACIDS IN THE FECES OF INFANTS: Jesse R. Gerstley (Amer. Jour. Disease Child., Vol. 40, July, 1930, Pages 27-45). The author is reporting on the influence of diet on the excretion of volatile, lactic and total titrable acids as well as on the hydrogen ion concentration in the feces of infants. Some eight years ago Gerstley and his coworkers started on their work with the supposition that the feeding of lactose in cow's milk would produce harmful effects upon the health of the child and would show in the stools, perhaps giving diarrhea. Their results to the contrary seem to indicate that the feeding of three per cent lactose in the milk mixture produces a decidedly beneficial effect both on the general health of the child and the character of the stools excreted. The child gains in weight, appears better, and the total amount of the feces is diminished. The general appearance of the stool, as well as the hydrogen ion concentration, changes to resemble that of the breast fed child.

Their observations were that the total amount of the stools of the child fed on cow's milk without lactose were more bulky than the stools of the breast fed child, also it is more alkaline in reaction—although the total amount of acid excreted in twenty-four hours is greater in the artificially fed child than in the breast fed. The feeding of a three per cent lactose in the milk mixture for a long time showed no diarrhea or any other harmful effects, but to the contrary showed improvement in the children so fed and at the same time the bulk of the stools, the general appearance of the stools as well as the hydrogen ion concentration of it resembled that of the breast fed child.

The feeding of a twelve per cent lactose in the milk mixture for several weeks produced symptoms of alimentary intoxication with a drop of weight but produced no diarrhea. The author therefore suggests that indigestibility of cow's milk is not responsible for diarrhea in childhood. He is also favorably impressed with the value of giving three per cent lactose in the milk formula.

In reviewing the literature the author notes two schools of thought:

1. One holds that gastro-intestinal influences such as pathological, chemical, bacteriological, or physiological changes lead to diarrhea and nutritional disturbances.
2. The other holds that diarrhea is secondary to a disturbance in metabolism and nutrition, especially from the work of Czerny and Finkelstein, who are directing more attention to general body metabolism. According to them diarrhea is a complication of a disturbance in general body metabolism arising from intestinal fermentation due to improper use of carbohydrates by the body.

Aaron Friedell, M.D.

IMMUNITY TO POLIOMYELITIS IN MOTHERS AND THE NEWBORN AS SHOWN BY THE NEUTRALIZATION TEST: W. L. Aycock and S. D. Kramer (Jour. Exp. Med., 53, 457, Oct. 1, 1930). Aycock and Kramer call attention to the fact that elsewhere they have presented evidence indicating that immunity to poliomyelitis is widespread, bearing a direct relationship to age and concentration of population, and in inverse relationship to the incidence of the disease in all age groups. They found the immunity to exist least often in the one to five year age group, and especially is this true in those of the rural districts.

In order to determine whether the relatively low incidence of poliomyelitis in infants is due to a temporary maternal passive immunity similar to that noted with respect to diphtheria, the authors tested the blood sera of a group of twelve mothers together with the sera from the cord blood of their newborn infants for the presence of neutralizing substance for the virus of poliomyelitis. The sera were mixed with the virus suspension, incubated for two hours, placed in the ice box over night, and inoculated intracerebrally into rhesus monkeys. The neutralization tests for the virus of poliomyelitis revealed that immunity was present in ten out of twelve infants, and in ten out of twelve mothers, with complete correspondence between the mother and infant. These tests point to passive transmission of an immunity to poliomyelitis from the mother to her infant. Previous tests on older children (one to five years), however, indicate that the passive immunity the infant receives from its mother is transitory.

C. A. Stewart, M.D.

STUDIES IN THE COMMON COLD: Experimental transmission of the common cold to anthropoid apes and human beings by means of a filterable agent. A. R. Dochez, G. S. Shibley and K. C. Mills (Jour. Exp. Med., 52, 701, Nov. 1, 1930). In this study of upper respiratory infection usually grouped under the heading of common cold, the author's primary interest was in its etiology. In earlier works two groups of organisms were investigated for possible causative relationship: (a) the bacteria more readily cultivated from the upper respiratory tract, and (b) the group of Gram-negative, filter-passing anaërobes first described by Oletzky and Gates. Dochez, Shibley and Mills found that colds may be transmitted to man and chimpanzee by intranasal inoculation of filtered nasal washings from which the filter-passing Gram-negative anaërobes of Oletzky and Gates were absent. They conclude, therefore, that certain types of infectious colds are caused by a filterable agent.

C. A. Stewart, M.D.

RAPIDITY OF IMMUNIZATION WITH DIPHTHERIA TOXOID: M. Cooperstock, M.D., Ann Arbor, Mich., and G. F. Weinfeld, M.D., Ravinia, Ill. (Amer. Jour. Dis. of Children, Nov., 1930, Vol. 40, No. 5). In a previous report, the authors submitted their results with the use of diphtheria toxoid, concluding that this material has a high immunizing value, and that, by virtue of certain important advantages that it possesses, it recommends itself as an ideal agent in vaccination against diphtheria.

In a group of fifty subjects, a negative Schick reaction developed in twenty-nine, or 58 per cent, three weeks after the second injection. In a second group of forty-four subjects, it was found that in thirty-five, or 79.5 per cent, the reaction had become negative in nine weeks. A third group, retested at the end of from sixteen to twenty-two weeks, revealed that of sixty-five subjects, sixty, or 92.3 per cent, showed negative reactions to the Schick test.

It has been the author's custom in the routine procedure for diphtheria prophylaxis with toxoid to use two injections of 1 c.c. each, with an interval of three weeks between injections. A third injection administered at the end of six months to those subjects who still give positive reactions to the Schick test, will probably be sufficient to immunize most of the small remaining number. Ramon and Helie stated that from 90 to 95 per cent are immunized in from five to eight weeks. Bloomberg and Fleming reported an immunity of 84 per cent at the end of eight months, with the employment of two injections of 0.5 and 1 c.c., respectively.

The interval between injections is a factor of considerable importance. Injections spaced too closely may bring about the so-called "negative phase" in circulating antitoxin and a delay in the production of immunity. For example, in a group of twenty-seven subjects, each of whom had received two doses of 1 c.c. of toxoid, with an interval of only one week between injections, it was found that the Schick test was negative in only 29.3 per cent from three to five weeks after the second injection. The result seems significant when compared with the much higher immunity of 58 per cent obtained after a comparable time with the same dosage, but with intervals of three weeks between injections.

It is suggested that the employment of two injections of 1 c.c. each, three weeks apart, is, for practical purposes, an adequate routine procedure in diphtheria vaccination. It is pointed out that spacing the injections too closely may delay the production of immunity.

R. N. Andrews, M.D.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

OBSTETRICS. J. W. Williams. 6th enlarged and revised edition. 1,157 pages. Price $10.00. New York: D. Appleton & Co., 1930.

It is quite impossible to offer any remarks of endorsement of this book in addition to that conveyed by the name of the author. This edition contains over 1,100 pages of reading matter, and it has many additional illustrations. The author devotes a rather lengthy chapter to that great question of cesarean section and the additional operations of sterilization and hysterectomy. He discusses very interestingly the low cesarean section. The book is brought up to date in all respects, even the latest tests concerning the early diagnosis of pregnancy.

A. G. Schulze, M.D.

THE BLOOD PICTURE AND ITS CLINICAL SIGNIFICANCE. V. Schilling, translated by R. B. H. Gradwohl. Price $10.00. St. Louis: C. V. Mosby Co., 1929.

For those interested in the value of nuclear changes in leukocytes as having a definite prognostic significance, this volume will prove of value. Schilling has simplified Arneth's classification, dividing the neutrophils into five groups according to their degree of maturity, as shown by the development of the nucleus. The appearance of youthful or immature forms he considers proportionate to the severity of the infection, and is supposed to be an index of the general resistance of the body. The author has gone into the interpretation of these variations in considerable detail. All other phases of hematology are given inadequate attention, as the author is obviously interested only in riding his hobby.

Thomas Myers, M.D.

MANUAL OF THE DISEASES OF THE EYE: Charles H. May, M.D. 13th ed. 461 pages with 374 original illustrations including 23 plates with 73 colored figures. Price $4.00. New York, Wm. Wood & Co., 1930.

This manual deservedly maintains its position as the most widely used work on the eye for students and general practitioners. It is now in its thirteenth edition in the United States, sixth British edition, eighth Spanish edition, fifth French edition, fifth Italian edition, fifth Dutch edition, second German edition, second Japanese edition, and second Chinese edition.

In this new American edition some chapters have been re-written, some altered, and some additions have been made in order to keep the book abreast of current practice. Five pages on the slit lamp and corneal microscope from the pen of Mr. T. Harrison Butler is a new contribution. This printing retains all the excellent features of the old editions, the clear lucid style, the profuse excellent illustrations and fine color plates, and the dependability of the subject matter. It is a work to be highly recommended for use by the student and the general practitioner.

Harold Rothschild, M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

FOR SALE—Instruments and office equipment of the late Dr. A. E. Comstock. See or address Dr. C. F. McNevin, 714 Lowry Building, Saint Paul, Minnesota.

PHYSICIAN'S OFFICE FOR RENT—Best location Midway district, corner Thomas and Hamline, Saint Paul. Rent $25.00 a month. Inquire at dentist's office.

FOUND—On road between Excelsior and Chaska, physician's bag containing instruments. Address Dr. C. K. Holmes, 702 Physicians and Surgeons Building, Minneapolis, Minnesota.

WANTED—Doctor to share office in Medical Arts Building. Office now available mornings and until 3 o'clock in the afternoon. Address D118, care Minnesota Medicine.

WANTED—By 1927 Minnesota graduate, an assistantship location or locum tenens in Minnesota. Can arrange personal interview. Address D117, care Minnesota Medicine.

EXCELLENT PRACTICE—Available immediately to purchaser of equipment and drugs. Small cash payment. Southwestern town and country over 500. Specializing. Address D-119, care Minnesota Medicine.

FOR SALE: North Dakota, large German practice, unopposed. Will consider only an industrious man. Address D-116, Minnesota Medicine.

LOCUM TENENS WANTED—Experienced, well qualified physician desires locum tenens. Registered in Minnesota. Address D-120, care Minnesota Medicine.

PRESENT THEORIES CONCERNING THE ETIOLOGY OF ACUTE RHEUMATIC FEVER*

Ralph A. Kinsella, M.D.
Professor of Medicine, St. Louis University School of Medicine
St. Louis, Missouri

THE researches of Swift and his associates have not only offered a new theory for the etiology of acute rheumatic fever, but have at the same time quickened the study of other infections from a new standpoint. Investigators are striving to evaluate the influence of allergy in the production of symptoms. It is being realized that a so-called infectious disease may not always present a group of symptoms resulting from the contact of the human body with pathogenic microörganisms, but may offer a clinical display, the result of a second contact which follows closely upon a previous experience of a similar kind. The factors which underlie this statement are not always clearly determined.

Acute rheumatic fever had usually been regarded as an acute infection which resulted from the single or first contact of the human organism with some bacterium. Many believed this bacterium to be a streptococcus; others held that the etiological agent was as yet unknown. It is significant that while the proof that a streptococcus was the cause of the disease was not widely accepted, no other form of bacterium was being considered as etiological. In an early communication, Swift and Kinsella[1] denied any causative relationship for the streptococcus even while reporting an incidence of 11 per cent of positive blood cultures. At the same time the reports of Rosenow[2] and Poynton and Payne,[3] describing a high incidence of positive cultures from blood and joints found only limited favor.

One of the chief obstacles to the ready acceptance of the streptococcus was found in the conviction that the pathology of acute rheumatic fever was specific and never found in other diseases in which streptococci were known to be active, such as subacute streptococcal endocarditis. This attitude was clearly defined in the arguments of Thalhimer and Rothschild.[4]

It is extremely interesting to note in how far the old attitude of doubt has been changed by the newer data and equally interesting to scrutinize these data and discover in how far they fail to be valid.

Swift[5] began by considering the similarity between the manifestations of acute rheumatic fever and those of tuberculosis and syphilis which are regarded as allergic. The inevitable inference was, that acute rheumatic fever employed the mechanisms of allergy. Then he observed for the first time[6] that living streptococci injected intradermally in rabbits produced not only an immediate inflammation, but, at a later date, a second milder inflammation which occurred even though no living streptococci could still be demonstrated in the skin. From this it could be inferred that streptococci could produce effects through allergy.

Finally,[7] patients suffering from acute rheumatic fever were found to give positive reactions to intradermally injected killed cultures of streptococcus. From this it could be inferred that the allergic manifestations of acute rheumatic fever were incited by the activity of streptococci, although intradermal reactions are uncertain tests of specificity.

The fact that allergy influences the reaction of the body is apparently true in another form of acute rheumatism in which the etiology is clear, namely gonorrheal rheumatism. If histories are carefully obtained in cases of this disease it is found that rheumatism never attends as an early accompaniment of urethritis, but occurs after several weeks or months have elapsed. In the meantime, gonococci are evidently alive but localized. Frequently an entirely unrelated event, such as an acute respiratory infection, seems to be instrumental in permitting the localized gonococci to invade the blood stream and produce acute vascular damage. A recent case illustrates this point. A young woman, known to have had pelvic infection a year previously, became ill with fever and acute inflammation of the throat. The tonsils were prominently enlarged and yielded rich cultures of streptococcus hemolyticus. A series of painful joints followed and after a week the wrist became acutely and persistently inflamed, although the signs in the pharynx subsided. No signs developed in the pelvis. The wrist was drained by incision and gonococci were isolated in pus and then found in urethral smears.

---

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, Minn., July 15, 1930.

In other words, the human body seems to have one set of reactions when it comes into contact with a disease-bearing bacterium the first time, but an entirely different response if it meets the same organism a second time while still under the influence of the first contact. This alteration of behavior is what is meant by allergy.

In the case of acute rheumatic fever a streptococcal pharyngitis may correspond to the gonococcal urethritis, and a secondary inciting cause such as an intercurrent infection, may precipitate a fresh contact between the body and the streptococcus which is attended by a diffuse vascular reaction recognized clinically as acute rheumatic fever. But a quite different mechanism may operate. In the case just described it is seen that a patient with chronic urethritis can acquire gonococcal rheumatism following an acute streptococcal pharyngitis. Likewise, animals suffering from chronic streptococcal arthritis without bacteriemia can display a positive streptococcal blood culture after acquiring the unrelated disease of "snuffles." In other words, the incident which precedes gonorrheal rheumatism need not be closely related, and the incident which precedes most cases of acute rheumatic fever, namely a so-called streptococcal pharyngitis, may in reality bear no bacteriological relationship to the disease. According to this last view the etiological agent would remain, and the sore throat be an accidental intercurrent disease precipitating the secondary reaction called acute rheumatic fever.

Therefore while there is little basis to doubt that allergy plays a part in the production of acute rheumatic fever, the relationship between the disease and a streptococcus seems to be based on the results of studies by Rosenow,[2] by Clawson[8] and more recently by Cecil,[9] as well as on the studies by Swift[10] just described. The chief remaining objection to accepting the streptococcus as the cause of the disease lies in the alleged specificity of the pathological lesion—the Aschoff body. In diseases known or thought to be caused by streptococci, such as subacute bacterial endocarditis and acute glomerular nephritis, no such lesions can be demonstrated. On the other hand Clawson[11] has declared that the perivascular lesions of rabbits inoculated with streptococci are similar to Aschoff bodies. In a rather extensive experience in this field of experimental endocarditis and experimental arthritis using both hemolytic and non-hemolytic streptococci, we have not been able to conclude that the lesions produced were identical with Aschoff bodies.

The pathology of acute rheumatic fever is that of widespread perivascular reaction, at first exudative and later proliferative, and having a highly specialized character. In its distribution it is similar to the lesions of chronic streptococcal infection in rabbits. The identity of the reaction in the rheumatic nodule, in the heart muscle and in the vessels near the joints has been established by von Glahn[12] and Pappenheimer and by Swift.[10] But the specific character of these lesions has not yet been clearly disputed.

Another objection to the acceptance of the streptococcus as the cause of acute rheumatic fever lies in the fact that the same organism is reported in many other conditions that are unrelated but sufficiently chronic to permit the development of allergy. Again, in a given blood culture from a patient with acute rheumatic fever it is possible to isolate different types of streptococci, in contrast with blood cultures in subacute streptococcal endocarditis where all the colonies are identical.

The modern tendency to emphasize the vascular diseases as primary and such peripheral disturbances as myocarditis, nephritis, and arthritis as merely local manifestations, weakens the idea of bacteriological specificity and makes it unnecessary to believe that a certain selective activity is required for each of these organs to be involved in chronic disease.

The rheumatic lesion of the blood vessels near a joint was found to be unaltered by the symptomatic relief given by neocinchophen.[10] In our studies[13] of the influence of sodium salicylate on the dermal reactions of rabbits which suffered from chronic focal streptococcal infection, it was found that although sodium salicylate prevented allergic dermal responses it in no way altered the character of the vascular lesions.

This effect of sodium salicylate in suppressing the allergic dermal reactions of rabbits may explain the apparent efficacy of this type of drug. By inference, it would indicate that most of the graphic symptoms of the disease, such as the joint pains and the serous effusions, are exudative and allergic activities, with which the drug can successfully interfere.

On the other hand, the failure of the drug to alter the proliferative vascular lesions in animals is in accord with the failure of the drug to prevent the proliferative cardiac lesions in human sufferers. Furthermore, since sodium salicylate does not alter the late pathology we are led to the conclusion that the allergic features of the disease are overlying secondary phenomena of little ultimate importance, while the infected focus, the tonsil, the sinus or some as yet unrecognized area, constitutes the underlying primary factor of great importance which is responsible for the proliferative, crippling vascular damages of this disease. Incidentally the prophylactic administration of salicylate or some related compound given at the time of any respiratory infection, should be most useful. The removal of tonsils and the drainage of the paranasal sinuses has so failed to prevent or arrest the disease that it is suggested that some entirely different atrium of infection is to be located in acute rheumatic fever.

Reviewing the evidence which is available, we can conclude that—

1. Acute rheumatic fever is an acute infectious process in which the body is coming into contact with the causative agent for a second time, while still suffering the effects of the first contact.
2. The evidence that this causative agent is some form of streptococcus is strong but not entirely conclusive.
3. A new approach by chemotherapy is invited by the studies of the effect of sodium salicylate on the allergic dermal phenomena in rabbits.

CORONARY OCCLUSION*

Herbert W. Rathe, M.D.
Waverly, Iowa

SUDDEN death due to heart disease seems to be steadily increasing, and coronary occlusion is the most common cause. Since 1920 attention has been focused on this subject and much outstanding work has been done by Herrick, Smith, Pardee, Barnes, and others.

The etiology of coronary disease is as yet not definitely known. Hypertension is no doubt an important factor; however, in my cases it has not been. Anatomical variations play an important part, especially the right angle branching of the left coronary artery, which differs from the branching of the right coronary artery that occurs in the same plane as its subdivisions. Beneke of Berlin believes that the tortuosity of the coronaries creates eddies in the flow of blood; the resultant strain on certain portions of the arteries causes a fibrosis which is a forerunner of occlusion. Others believe that infection plays an important rôle, and no doubt it does in certain cases, syphilis especially.

The pathology of coronary occlusion is myocardial infarction of varying degrees, depending upon the size and location of the artery and the question of whether the occlusion is gradual or sudden. This infarcted area may undergo fibrosis or it may thin out, form an aneurysm, and rupture.

As a rule the onset is very sudden. A large number of these patients will tell you that for some weeks or even months they have had "little twinges of pain" or short attacks of dyspnea and dizziness. The typical picture is that of very severe pain which lasts for some time, often twenty-four hours, and which requires large doses of morphin for even partial relief. The pain may be very slight and the patient complain only of retrosternal constriction, a heavy feeling, or, as some may call it, a discomfort. The areas where the pain is witnessed vary; most often the pain is retrosternal or precordial and may radiate to the neck or to one or both arms. However, it may be referred to the epigastrium, wrist, elbow, or, as in one case I have seen, to the sacral region. Sometimes the patient's complaint will be only of dyspnea or orthopnea; at other times these symptoms will accompany the pain. Nausea accompanied by vomiting sometimes is complained of, and if the pain is in the epigastrium a differential diagnosis from an upper abdominal lesion is very difficult.

On examination the patient presents a very anxious facial expression with a peculiar ashen cyanosis. Several whom I have seen were transfixed with the pain and would not move from the position they were in, no matter how uncomfortable. If the attack is at all severe, shock is a marked feature with a cold clammy sweat and a fall in blood pressure, often to as low as 60 mm. Hg. systolic. The pulse is weak, rapid, and at times irregular. The heart sounds are distant and may be inaudible; a friction rub and alteration of rhythm occur at times. The signs of early congestive heart failure appear in some cases; then one finds râles at the lung bases, an enlarged and tender liver, and albumin in the urine. After twelve to twenty-four hours there is usually a rise in temperature (99.5° to 101° F.) and a leukocytosis (12,000 to 16,000). Emboli to other parts of the body or repeated coronary emboli are apt to occur following the occlusion.

Electrocardiographic evidence is most often conclusive, especially so when repeated tracings on successive days are taken. I have studied thirty-two cases with the electrocardiograph up to the present time, and in my opinion my chief errors have been in not heeding what I would call only minor evidence. The most typical changes are in the R-T segments with a depressed and inverted T in either leads I or III and an elevation in the opposite lead. An inversion of the T wave in lead III alone is not important, but if there is inversion of this segment in lead I or II it is very good evidence of coronary disease. Other signs of coronary involvement are bundle branch block and notching of the QRS with low voltage.

The prognosis in cases of coronary occlusion varies greatly. The average of several large groups of cases shows that about fifty per cent die during their first attack. It is said that the older the patient the better the thrombosis is tolerated. This is due probably to the compensatory circulation formed by the Thebesian vessels as well as by anastomosis between various portions of the coronary system. Many of these patients recover and never have another attack; others will die in a second or third attack or develop a congestive heart failure. There are many who are still alive following attacks eight to ten years ago of what undoubtedly was coronary occlusion. It is well worth our while to remember that some of these cases are not fatal and are worthy of our best efforts in treatment.

---

*Read at the annual meeting of the Southern Minnesota Medical Association, Mankato, Minn., August 25, 1930.

The acute case should have absolute bed rest with sufficient morphin to relieve the pain. When the severe pain has subsided another sedative may be substituted for the morphin, but bed rest must continue for a considerable time. Favorable conditions for extending the patient's activities are a return of the blood pressure level to near normal, improved quality of the heart sounds, absence of subjective symptoms, and, if an electrocardiograph is available, an improvement in the electrocardiogram. Theobromin, theophyllin, and euphyllin are drugs which are used to promote coronary circulation. Experimentally euphyllin has proven the most efficient and clinically I believe it is the most satisfactory. Digitalis is not indicated in the acute stage.

CASE REPORTS

Case 1.—A man, sixty years of age, who had been an office man for years, was first seen by me on April 2, 1930. His family and past medical history was irrelevant. There was no previous hypertension to his knowledge. He did not smoke and was moderate in his exercise. On the evening of March 28, 1930, he had a severe pain in his upper abdomen, which lasted for about an hour. He was nauseated and vomited but got no relief on vomiting. He thought it was acute indigestion. He was in moderate shock, and his blood pressure was 118/78. The heart sounds were distant and of poor quality; there was no friction rub, fever, or leukocytosis. On April 2, 1930, his electrocardiogram showed a negative T wave in lead III and a rounded elevated R-T segment in lead III. On May 21, 1930, he had a negative T wave in both leads II and III. He has been on bed rest most of the summer and at present from all indications is doing well.

Case 2.—A man, forty-seven years of age, had been a machinist for twenty-five years. His father died suddenly at the age of sixty-six years; his death was said to have been due to heart failure. The patient had never been ill before except for a mild attack of influenza in 1918. On December 9, 1929, he had an attack of knife-like pain retrosternally, had marked dyspnea, and could not move for about ten minutes. An uneasy sensation persisted for four days when he had another attack which lasted an hour and radiated to both arms. He had had several attcks since, the most severe one on January 29, 1930, which lasted for twelve hours. Following this there had been a numb sensation in both arms up to February 2, 1930, when I saw him first. At that time he was very ill. The ashen cyanosis mentioned above was marked, and he was very apprehensive. His pulse was very weak, and the heart sounds could hardly be heard. There was no friction rub. There were râles at both lung bases, the liver was enlarged and tender, and there was albumin in the urine. His blood pressure was 108/86, temperature 99.8° F., and leukocytes 12,000. An electrocardiogram showed a negative T wave in leads I and II. He had several more attacks with increasing congestive heart failure and died two months later. An autopsy at the State University Hospital revealed coronary thrombosis with myocardial infarction.

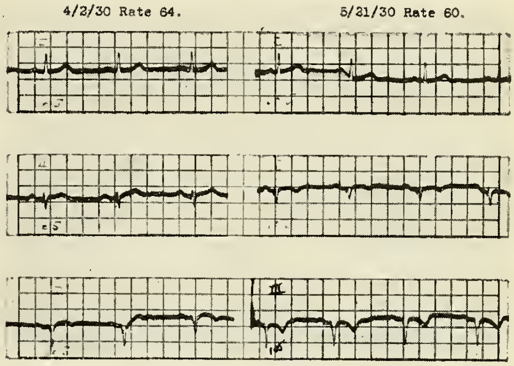

Fig. 1. Case 1.

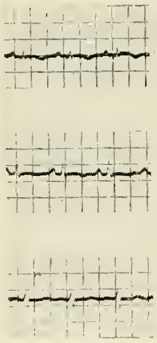

Fig. 2. Case 2.

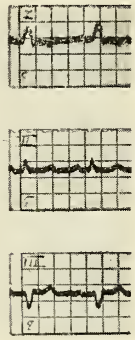

Fig. 3. Case 3

Case 3.—A woman, forty-nine years of age, had been a school teacher for a number of years. She had hyperthyroidism in 1918 and a thyroidectomy had been performed with relief. In December, 1928, she again had hyperthyroidism and was relieved by surgery. At this time her blood pressure was 160/68. Her convalescence was uneventful and she felt fine. On March 14, 1929, while hurrying to a train, she had a severe retrosternal pain radiating to the left elbow. On April 24, 1929, she was weak, listless, and dyspneic on the slightest exertion. Her color was good, pulse regular, and rate normal. The heart examination revealed a systolic murmur along the left sternal border and a split first sound at the apex. Her blood pressure was 148/108. Her electrocardiogram revealed a complete bundle branch block. She remained in bed for three months and her activity was limited for a year. She is now teaching and apparently is in good health.

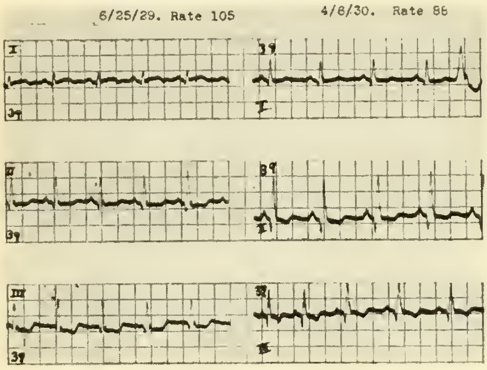

Fig. 4. Case 4.

Case 4.—A man, thirty-seven years of age, whose occupation was farming, consulted me in June, 1929. From December 26, 1928, to January 1, 1929, he had had a mild attack of influenza. On January 6, 1929, he had a severe retrosternal pain lasting from 7 A. M. to 9 P. M. During this time he was dyspneic, perspired freely, and was said to have been very pale. For several weeks following this he had a tight feeling in his chest, but went about his work. On June 22, 1929, he again had pain in the same region, which he thought was even more severe. A physician was called, and a hypodermic was given with some relief. The pain was some better, but was present when I first saw him on June 25, 1929. At this time ashen cyanosis was very apparent and he looked very ill. His pulse was rapid and thready, temperature 101.4° F., and blood pressure 108/86. The heart was enlarged to the left; the point of maximum impulse was diffuse, and his heart sounds were of poor quality. The electrocardiogram at this time showed a depressed R-T in lead III and not so marked in lead II. He was in bed for eight weeks and was up in a chair for four weeks when I again saw him. His blood pressure was 140/108 and his pulse 76; the electrocardiogram was normal. Restriction of activity was advised. He reported again April 6, 1930. At this time he was dyspneic on exertion, had an uneasy sensation retrosternally, and had a numb sensation in both arms. His pulse was 80 and his blood pressure 146/100. The electrocardiogram showed a negative T wave in leads II and III. I sent him home on another course of bed rest, which he did not follow. He had a severe attack while working on May 10, 1930, and expired.

SUMMARY

Coronary occlusion is probably more common in recent years than ever before. It has a definite pathology, a variable clinical picture, and usually a characteristic electrocardiogram. The disease is not always fatal, and if the patient survives the first attack and will follow a regimen of rest and limited activity the prognosis is good. Four cases with electrocardiograms are reported from a series of thirty-two.

SOME CLINICAL FEATURES OF CHRONIC PULMONARY FIBROSIS*

ARTHUR T. LAIRD, M.D.
Nopeming, Minnesota

THE formation in the lungs of new fibrous tissue, while it results from various causes, produces similar clinical phenomena in different diseases and conditions. In certain cases it so masks the symptoms that would otherwise occur that diagnosis is difficult and it may even conceal the primary disease entirely. In other cases it adds to the basic symptoms of the disease, conditions that are symptomatic only of fibrosis.

In this paper while discussing briefly other forms of lung fibrosis, I want to emphasize the changes produced by fibrosis in the clinical picture of tuberculosis, and the necessity of directing the treatment of a case accordingly.

Fibrous tissue is normally present in the body in tendons, ligaments, aponeuroses, fasciæ, in various gland capsules and in certain membranes such as the dura mater. These tissues are composed almost wholly of dense bundles of white fibrils having a course nearly parallel. Between the fibres is ground substance in which are found the cells, irregular and often elongated in form. They are supposed to secrete the ground substance and to be the origin of collagen, which can be converted into glue.

Fibrous tissue is one form of connective tissue and so is related to mucous, reticular and adipose tissue as well as to cartilage and bone, which may sometimes be found in connection with pathological fibrosis.

The abnormal production of fibrous tissue in the body may result from congestion, irritation and from the destruction of parenchyma or other tissues. It may thus be a phase of inflammation. Foreign bodies, dust particles, bacteria and chemical poisons may give rise to it. It is often an attempt on the part of the body to isolate dust particles or disease foci, or to replace destroyed areas with scar tissue. Once under way the formation of fibrous tissue may proceed further than the needs of the body require and become a detriment instead of a benefit.

There are various theories as to the origin of the new fibrous tissue. The majority of pathologists believe it to be derived from fixed connective tissue cells which thus become fibroblasts. Baumgarten, Metchnikoff, Maximow, Krause and others have studied the problem assiduously. The fixed connective tissue cell may be the common ancestor of the fibroblast and of the monocytes of the circulating blood. There have been some attempts to link fibrous tissue formation with cells of the blood or lymph but it is more generally believed that the fibroblast and the epithelioid cells of tuberculosis, arise from old connective tissue cells in situ.

As regards the exact source of the dense fibrils the usual opinion is that they arise from transformation of the fibroblasts, though Baitsell and others consider them to result from a process analogous to clotting taking place in the intercellular substance.

Three chief forms of lung fibrosis may be recognized: the local, involving limited areas in one lung; the diffuse, involving large continuous areas which may extend throughout the greater part of a lung, or even involve both lungs; and the disseminated or generalized, which consists of the presence of scattered fibrous nodules widely distributed, usually through both lungs.

The localized form may be caused by tuberculosis, and other infections, especially when they produce lung abscess. Echinococcus infestation of the lung usually produces it. It follows obstruction to the air passages in atelectasis and infarct. Areas of broncho-pneumonia may become fibrosed. Extra pulmonary conditions such as aneurysm and mediastinal growths may produce it by pressure.

More diffuse fibrosis occurs in tuberculosis, syphilis, influenza, croupous pneumonia and in other infectious diseases. Purulent pleurisy is followed by lung fibrosis more frequently than is generally appreciated. Exposure to irritant gases is said to set in train a course of pathological changes which may ultimately result in the formation of extensive areas of fibrous-tissue.[2] Croupous pneumonia sometimes fails to resolve though less frequently than might be thought; chronic passive congestion sometimes results in "brown induration." Collapsed lungs if long remaining in that state may become extensively fibrotic.

---

*Presented at the annual meeting of the Minnesota State Medical Association, Duluth, July 15, 1930.

Pneumoconiosis has been known to the profession for centuries. Paracelsus wrote a book on it. This disease of the lung due to inhalation of various kinds of dust is common but the effects vary with the kind of dust inhaled. Organic dusts are not believed to produce lung fibrosis. Inorganic dusts even vary greatly in the changes produced. Stone cutters, miners of metals found in flinty rocks, grinders and polishers are the most frequent sufferers from miners' phthisis. Coal dust seems to be relatively harmless.

Mycosis of the lungs is claiming more and more attention.

Spirochetal infections frequently produce pulmonary gangrene. Vincent's organism is held responsible in some cases. Infections with yeast-like organisms apparently more often produce fibrosis.

Castellani has prepared quite an elaborate classification based on his experiences in Asia.

The main divisions are: (1) mycosis due to yeast-like fungi; (2) mycosis due to filamentous fungi.

Yeast-like fungi include, among others, blastomyces, cryptococcus, and the monilia (which causes "tea tasters cough"). Due to the filamentous type are the aspergillus infections. These are the cause of pigeon crammer's disease and probably also of an interesting form of lung disease of which Sayers and Meriwether reported 125 cases at the Annual Meeting of the National Tuberculosis Association held in Memphis in May, 1930.

Other fungi which may cause pulmonary mycosis are the various kinds of streptothrix, the actinomyces, and the coccidioides immitis or oidium coccidioides, which is responsible for a disease resembling tuberculosis, of which about a hundred cases have been reported. Most of these have occurred in southern California.

Fungi may be present in the lung as saprophytes, as secondary invaders or as the primary cause of lung disease. While in some cases the symptoms produced resemble those of active tuberculosis, in others the progress of the disease is very slow and its course may be characterized by extraordinary fibrosis.

Carcinomata form the largest group of pulmonary neoplasms. Miller and Jones, discussing primary carcinoma of the lungs, mention two types often confused with tuberculosis. The first is the scirrhous type of disease, which resembles fibroid phthisis. The second is miliary carcinosis, which resembles miliary tuberculosis. In primary carcinoma of the lung the use of the bronchoscope in order to secure tissue for biopsy sometimes clears up the diagnosis. Secondary tumors in the lungs are more common and more readily diagnosed.

Though the causes of lung fibrosis may thus be varied, the pathological findings and the *x*-ray pictures produced may be very similar.

Any part of the lung may be the starting point of fibrosis, the tissue about the bronchi and blood vessels, the interlobular septa, the alveolar walls or the pleura. In the early stages of generalized fibrosis there is peribronchial thickening at the root of the lung; later the parenchyma becomes involved. Affected portions on removal are found to be hard and airless and to resist cutting. The fibrous areas consist of dense grayish tissue which may be most prominent at the root of the lung with radiating bands extending out into the lung especially in non-tuberculosis fibrosis. In the tuberculous form, the process often involves the apex. The pleura is frequently involved and much thickened; apical cavities are often present in the tuberculous form and have thick walls. Dilatation of the bronchi and bronchiectasis occurs in extreme cases. The heart eventually becomes displaced toward the affected side. If the fibrosis is extensive, unaffected areas become emphysematous. Where the fibrosis is widely distributed and consists of multiple areas of dense tissue surrounding scattered implantations of irritating substances, small dense nodules are found embedded in comparatively normal pulmonary tissue. In *x*-ray films various forms of generalized fibrosis may simulate miliary tuberculosis.

The symptoms can be to some extent inferred from the pathological findings. At first the scattered areas of fibrosis may so efficiently enclose the offending foreign bodies that there may be no symptoms whatever, although the disease is progressing. When the cause is not removed, this latent increase in fibrous tissue may continue insidiously for months or even for years. It is especially prolonged in pneumokoniosis. In silicosis it lasts for years. In tuberculosis, even when the disease is not thoroughly arrested, toxemia may be prevented by fibrosis to such an extent that ability to work is lessened but little and the patient may consider himself well, though expectorating tubercle bacilli. A considerable period of freedom from symptoms is also characteristic of pulmonary mycosis.

When the fibrosis has become further advanced dyspnea becomes a prominent symptom. The patient becomes susceptible to repeated colds and to pneumonia, may develop emphysema, chronic bronchitis and bronchiectasis, have cough and expectoration, and even hemoptysis, but in spite of all these symptoms suggesting tuberculosis, he usually has very little or no fever and considers himself in fair general health, though the duration of the fibrosis may have been many years.

The diagnosis of the various forms of lung fibrosis is often difficult. Resemblance to tuberculosis in their clinical course causes difficulty. Repeated sputum examinations may lead to suspicion that tuberculosis is not present or to the finding of the organism responsible for the condition. Occupational history is most important. The site of the lesion is suggestive, the nontuberculous conditions being more frequently at the base than at the apices of the lung. The use of potassium iodide in some of the mycotic infections may be a therapeutic test.

A circumstance that gives rise to much confusion is the fact that tuberculosis is often a complication of other forms of chronic lung fibrosis.

The *x*-ray brings out shadows which are more or less characteristic. Many of them are common to fibrosis in several diseases. They consist of dense hilum shadows and prominent bronchovascular trunks, or of more massive opacities, thickened interlobar septa, broad shadow bands, disseminated nodular opacities, areas of lessened opacity (emphysema), dilated bronchioles and later the outlines of bronchiectatic cavities and of displaced structures.

Three typical forms of chronic fibrosis readily confused are those due to tuberculosis, to dust inhalation and to mycosis. The predominance of fibrosis in a tuberculous lung alters the clinical picture of the disease so completely that it is most important for the physician to be familiar with its effects, one of the most striking of which is the concealing of all evidence of the presence of the disease.

Physical signs and *x*-ray findings may be present for years in cases long since arrested and practically well. There is no advantage to be obtained by placing such individuals under the rest treatment or sending them to sanatoria. Upon careful inquiry it may many times be ascertained that such individuals long ago had such treatment and profited by it.

In other cases the disease is insidiously advancing in spite of lack of symptoms and the patient may be a carrier and distributor of germs in spite of apparently good health.

In the later stages of fibroid phthisis the picture may be so much that of chronic bronchitis and emphysema from other causes, that the physician is completely thrown off his guard. Area tuberculin testing of school children has led in many instances to an unsuspected adult as the cause of infection of a considerable group of contacts. Grandmothers on account of their close association with children are especially likely to be the guilty parties.

The most practical method of locating these unsuspected spreaders of disease seems to be to give the tuberculin test to large groups of children and then examine thoroughly all adult members of families in which reactors occur.

Other diseases characterized by fibrosis may have few symptoms for a long period. The importance of physical examinations at intervals is evident.

CAUSES OF DEATH FROM ACUTE APPENDICITIS*

Archibald L. McDonald, A.B., M.D., F.A.C.S.
Duluth, Minnesota

TWENTY-FIVE thousand persons die each year from acute appendicitis, according to figures from the Bureau of Vital Statistics. This exceeds the number caused by ectopic pregnancy, pyosalpinx, gall-stones, pancreatitis, splenic and thyroid disease, combined. It is fifty years since Reginald Fitz published his classic description of acute appendicitis, and surgical treatment was seriously proposed. Since then countless studies have been published, and it would seem that ideas on the subject have been well crystallized. However, statistics quoted by Quain[1] and by Sivertson[2] indicate that the death-rate from this cause has increased during the last decade. This in contrast to experience with other surgical conditions.

The present study is based upon the records of the fatal cases of acute appendicitis which occurred during the past five years at St. Mary's and St. Luke's Hospital in Duluth. Its purpose is to determine, as accurately as possible, the factors which contributed to the outcome; and to discuss means by which these might have been avoided or more successfully attacked. Seventy cases are included, twenty-five of which came to autopsy.

Table I

	Total Cases	Deaths	Per Cent
Surgical Cases	32,954	724	2.3
Acute Appendicitis	1,574	70	4.5
Percentage of Total	4.7	10	

These figures show that ten per cent of the surgical deaths were due to acute appendicitis, a condition which accounted for less than 5 per cent of surgical patients admitted to the two hospitals.

Except for the fatal cases, the records of the hospitals do not permit division of the 1,574 cases into those limited to the appendix and requiring no drainage, and those with some degree of peritonitis or local abscess formation. For the purpose of this study I have developed tables, using the percentages given by Quain and by Wallace.[3]

Of the seventy fatal cases, the notes indicate that in seven the process was limited to the appendix and in only two was there any evidence of peritonitis or sepsis during the post-operative period or at autopsy. Of these seven, three involved elective interval appendectomy and probably should not be included in this report. Death was due to extraneous causes as follows: (1) sudden syncope on the tenth day, clinically a pulmonary embolus; (2) hemiplegia in a man fifty-two years of age after 10 days of normal convalescence, together with severe bronchitis; (3) late post-operative pneumonia with empyema in a woman aged twenty-three, following an elective operation for a mild subacute attack, and death eight weeks following operation. The remaining four cases were operated upon early in an acute attack. Two presented serious complications which were important factors in causing death. One of these, a diabetic girl of seventeen, fairly well controlled by diet and insulin, developed a severe cold, then an acute abdomen with collapse so severe as to suggest acute pancreatitis or ruptured gastric ulcer, and required immediate surgical intervention. A gangrenous appendix was removed under ethylene anesthesia. In spite of active post-operative treatment with glucose and insulin the patient went into coma on the third day, developed edema of the lung and died. Autopsy was negative except for an acute edema of the lung and absence of the islands of Langerhans. The other, an acute alcoholic, aged fifty-seven, suffered a sudden attack and came to operation within twenty-four hours. Post-operative delirium and marked distention appeared and the patient died on the fifth day. In the other two cases death was frankly due to peritonitis and sepsis. One, with post-operative paralytic ileus and late enterostomy, died on the sixth day. Autopsy disclosed generalized streptococcus peritonitis. In the other, the wound broke down on the tenth day with a fecal fistula, fever persisted throughout, and death occurred on the sixteenth day. Autopsy disclosed a pelvic, and also a perirenal abscess. It is probable that both of these should have received immediate drainage, and one of them an early enterostomy.

*Read before the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, July 15, 1930.

TABLE II

	LOCALIZED				PERITONITIS					
			Mortality				Mortality		TOTAL	
	No.	Per Cent	No.	Per Cent	No.	Per Cent	No.	Per Cent	Deaths No.	Per Cent
Quain 1,000	551	55.1	2.	0.36	449	44.9	25	5.5	27	2.7
Wallace 600	398	66.3	2.	0.5	202	33.7	11	5.4	13	2.1
Total 1,600	949	59.	4.	0.42	651	40.7	36	5.5	40	2.5
DULUTH 1,574	944	59.	7.	0.74	630	40.	63	10.	70	4.4

Of these seven deaths, three were really late interval operations, of which two were embolic and one was due to late post-operative pneumonia. Two were due to known independent concomitant disease as the chief factor, and two were due to ileus and sepsis, and should have had more extensive primary operation.

On the basis of comparative figures, if the entire series of sixty-three late cases could have been brought to operation before extensive disease had developed, but five deaths would have resulted insteady of sixty-three, or a total of 12 for the 1,574 cases instead of 70. Therefore, the most important cause of death was late surgical intervention. We find four reasons for this:

1. The rapid course of the disease. Active peritonitis was found at primary operation in twelve cases within twenty-four hours of onset, and in eight others within forty-eight.

2. Failure to make a prompt diagnosis. Eight patients had been under medical care for more than twenty-four hours before a diagnosis was made and operation offered. Several of these apparently advanced to active peritonitis while under observation. We must ever keep the facts before us; the disease is frequently virulent and rapidly progressive, and as yet we have no fixed or positive evidence to identify these cases. Immediate operation as an emergency is the only justifiable course, certainly in the early cases, provided due consideration is given to possible complications or concomitant disease.

3. Failure to seek medical attention. Twenty-eight of these patients had been ill with suggestive symptoms for from three to ten days before calling a doctor. Twelve were known to have received cathartics. All were markedly septic when coming to operation. Surely the public is in need of education on this important subject.

4. Surgical intervention was delayed in six cases after the diagnosis had been established, twice, at least, justifiably. However, in only one instance was a well planned expectant treatment followed. While such a course is advocated by some experienced men for a certain group of cases with active or the "forbidding peritonitis" of Deaver, the Crile-Ochsner-Murphy plan of treatment must be rigidly followed.

Of the sixty-three fatal cases with peritonitis at the time of operation, the predominating causes of death are classified: (1) cardio-vascular—two; (2) pulmonary—twelve; (3) sepsis, including ileus—forty-nine.

The two cardiovascular deaths were as follows: A man, aged fifty-two, had been ill for six days before undergoing appendectomy with drainage. On the seventh day of satisfactory convalescence, he presented the clinical picture of an embolus and died suddenly. There was no autopsy. A man, aged sixty-nine, had an appendectomy with drainage on the second day of his illness, had a satisfactory convalescence till the fifth day, when he had a hemiplegia and died. Autopsy demonstrated cerebral thrombosis.

Of the twelve deaths with predominating pulmonary symptoms, three were embolic in origin, three presented evidence of pulmonary lesion before operation, and six developed late post-operative pneumonia. The embolic cases occurred on the fourth, sixth and seventh days of convalescence. One developed sudden collapse with pulmonary edema, and the other two were proven at autopsy. One of the latter also had a large retrocecal abscess which had not been reached by drainage. Three patients presented unmistakable evidence of pulmonary lesion previous to operation. One was unrecognized and was subjected to ether anesthesia for a prolonged operation of seventy-five minutes for appendectomy and drainage. Pneumonia was diagnosed the next day and death occurred on the second post-operative day. Another received a short chloroform anesthesia because of suspicious lung findings, developed bronchopneumonia and died on the third day. A third patient was explored and drained under local anesthesia during the course of a known pneumonia. Death occurred the next day and no autopsy was permitted. Three other patients developed pneumonia within forty-eight hours of operation, which lasted from forty to seventy-five minutes with ether anesthesia, which may have been a direct cause of the complication. The other three occurred later, following operation in cases which were heavily prostrated with sepsis and peritonitis. These may have been metastatic or asthenic.

More care in pre-operative study, selection of anesthetic, and protection during and after operation, would have prevented some of these deaths. Local or spinal anesthesia, better planning of operative procedures, early use of the oxygen tent, and proper post-operative protection must be given serious attention.

The remaining forty-nine patients died because of direct effects of the disease, namely: ileus or peritonitis with sepsis. Three were hopelessly toxic and obviously overwhelmed by infection when admitted to the hospital. Fairly well conducted expectant treatment was carried out in one instance for two days in an effort to secure some degree of improvement. Then under spinal anesthesia, drainage was attempted, resulting in death on the table. Another patient, who had been ill for a week, came in moribund, was operated on at once under local anesthesia for drainage and died on the table. A third individual, who had been sick for six days, was subjected to sixty minutes of ether anesthesia for appendectomy and drainage, and died a few hours later. These deaths seem to have been inevitable, but better pre-operative study and judgment would have averted ill-advised operative attempts.

Ileus was an outstanding feature in fourteen of the cases, though peritonitis and sepsis, to a marked degree, were also present in all. Five of these patients, previous to operation, presented such marked distention as to suggest the presence of ileus. In fact, in two instances, the pre-operative diagnosis was given as "intestinal obstruction." Primary ileostomy in addition to appendectomy and drainage was done in both of these, and also in another of this subdivision. The other two patients were badly distended previous to operation. This together with other evidence of ileus persisted till death. While early enterostomy is advised in all cases of ileus, the results are not as promising in cases associated with or due to extensive peritonitis.

One patient developed strangulation of an inguinal hernia on the sixth day following removal of a gangrenous appendix and drainage. Under spinal anesthesia, the hernia was reduced and repaired, and high enterostomy performed, but death occurred twenty-four hours later.

Eight other patients with extensive peritonitis and severe sepsis, also presented marked evidence of ileus, namely: paralysis of the intestinal tract, progressively increasing distention, persistent emesis finally fecal in type, and in three instances bloody discharge from the wound. In two cases enterostomy was done, rather late and without effect. In the usual case of post-operative paralytic ileus, early enterostomy is a valuable procedure. In certain instances of acute appendicitis with beginning ileus, primary enterostomy is indicated, and is often a life saving measure. It adds no burden to convalescence. To be of value it must be done before the gut is entirely paralyzed. In cases far advanced with peritonitis and sepsis, but little benefit can be expected, since peristalsis is no longer present or indeed possible.

In thirty-two cases peritonitis and sepsis must be accepted as the cause of death. It was an important contributing factor in those with ileus and with pulmonary complications. In nine instances, local or generalized peritonitis was drained without removal of the appendix, though in several much valuable time was expended attempting to do a complete operation. In ten cases the notes indicate some degree of localization of peritonitis at the primary operation. In all of these, the process continued to extend. In four instances autopsy disclosed localized abscesses which had not been reached by drainage.

Consideration of this entire group of extensive cases brings out several important questions:

1. That of immediate operation or expectant treatment. In this series there are a number of records which indicate that operation did little to control or limit the septic process, if indeed it did not actually hasten its extension. We must learn to recognize "the forbidding peritonitis" as recently re-described by Deaver.[4] This may be local or general and there is undoubtedly a stage of the process where operative manipulation is likely to do more harm than good. We must study again the classic descriptions of Murphy, Ochsner and Crile, and learn how, in certain carefully selected cases, we can best assist nature to localize and control the inflammatory process. In these, drainage is delayed till a carefully chosen time and then is a simple procedure.

2. Pre-operative preparation. While we recognize the fact that acute appendicitis calls for emergency operation, this is not necessarily true for acute peritonitis. We are forced to the conclusion that several of these patients were subjected to prolonged operation without adequate preparation. Certainly, some delay to overcome shock of travel, prostration, dehydration, if not to secure localization, would have contributed to a more successful outcome.

3. Prolonged anesthesia is always depressing, especially in the presence of sepsis. Yet most of these patients were given ether, or ethylene with ether, for from forty to ninety minutes, which certainly added materially to the operative burden. Local anesthesia, or local, reinforced by nitrous oxide to permit of a short well conducted operation would be preferable. Spinal anesthesia offers ideal facilities for all proper operative procedures, with no serious contraindication except prostration in presence of severe sepsis.

4. Operative technic. This is impossible to judge fairly from the notes in the hospital records. One derives the impression, however, that in most of the cases there was too much manipulation, too little protection of uncontaminated peritoneum, and too much time and energy expended in removing a deep-seated appendix. Also that in many instances more mature experience would have spared the patient much danger.

5. Drainage. Our observations from this standpoint bring out the fact that the classic studies of Yates, Blake, Coffey, and many others have need to be studied again, and again, and again. Too many operators still believe that free fluid, or even free purulent fluid, necessarily means infection of the entire peritoneum, and make no effort to wall off the truly septic area. In spite of all the published proof to the contrary they still have a childlike faith in the capabilities of two or three cigarette or gutta-percha drains as a means of relieving generalized peritonitis. Some of us must materially revise our ideas on this question.

6. Post-operative care given these patients is only sketchily outlined in the notes. It is quite apparent that many fail to appreciate the fact that operation is only one step in treatment. Some attempt to do too much, many do little or nothing. Few, however, have followed out a well organized plan conducive to localization of the septic process, overcoming shock and acidosis, and preventing ileus.

CONCLUSION

There is no classic picture of acute appendicitis which will fit any large number of cases. As physicians, we must appreciate the dangers of procrastination. Prompt diagnosis, careful attention to possible complications, and immediate appendectomy is the only safe course. It is the major hope of materially reducing the heavy mortality of this disease. There is need of a campaign of education for physician and layman bringing out the terrific dangers of delay. The so-called late cases often occur surprisingly early in the course of the disease. Proper management calls for a high degree of mature clinical judgment, and wide experience in operative procedure. Study of the operative notes and results force one to the conclusion that all of us have need to revise our ideas concerning treatment and drainage of appendiceal peritonitis.

THE PROSTATE IN A GENERAL EXAMINATION*

A. E. Sohmer, M.D.
Mankato, Minnesota

The routine general health examination as a prophylactic measure has been emphasized in recent years, and rightly so, in all medical bodies, as well as in public lectures and writings to the laity. Likewise, in the regular examination of every new sick patient, it is proper to make a reasonably thorough survey of the condition or functional capacity of the various organs and systems of the body. The extent of this examination depends somewhat on the object in view, and as the case develops there will be suggested the direction of these inquiries.

The Old Line Life Insurance examination, as the result of actuary statistics, has been standardized, covering quite well the history and the physical examination of the various important systems of the body, and might well be taken as a model on which to plan an examination—details to be worked out according to the findings in each case.

In a life insurance examination, answering the prescribed questions usually satisfies the company. In private work we usually go further, especially if obscure symptoms are in evidence, inquiring into the status of more obscure organs, because the private patient is interested not only in life but in comfort and well-being.

I wish, at this time, to call attention to the prostate gland as a source of disease, and one which is apt to be slighted in the routine of a physical examination. Every male patient who comes up for examination should have a rectal examination to determine palpable rectal pathology, and the condition of the seminal vesicles and the prostate gland—especially chronic prostatitis and the obstructing prostate.

When one mentions chronic prostatitis, the thought comes at once of a venereal disease, past or present; but this is not necessarily so, since a great proportion of cases are non-venereal, the prevailing bacteria being streptococci or staphylococci, rather than gonococci. It is true that gonorrheal prostatitis is quite prevalent and usually becomes a mixed infection in due time; but there is a class of cases of chronic infection of the prostate due to non-venereal origin, to which I would like to call attention at this time. It may be the cause of painful joints or muscles and ligaments, or an iritis, or an exhaustion syndrome with anemia, in the advanced case.

The infection in the prostate may be secondary to tonsillar or dental infection and is transmitted through the blood stream—remaining in the prostate as a latent focus, from which it infects distant joints or organs. This spread from the prostate is usually intermittent, being activated by a lowered resistance or by local irritation. Such a condition may exist for years. When discovered, and treatment is begun, the distal symptoms are often temporarily aggravated—just as the removal of a chronic infected tooth will make a person temporarily worse; this result can be of diagnostic importance. We may have a bacterial prostatitis without the presence of pus in the secretion, yet enough to cause distinct symptoms; in fact, until pus appears, the symptoms may continue. To determine such bacterial prostatitis, repeated massage after irrigating the urethra is required.

Von Lackum, who made intensive studies of this condition at the Mayo Clinic, found that approximately one-half of the cases of prostatitis under his observation were due to dental or tonsillar infection, and other distant foci. He found the most frequent organisms present were: the streptococcus in 35 per cent, staphylococcus 22 per cent, with about one-third of the cultures sterile.

One should always consider the prostate as a possible focus of infection in arthritis, neuralgia, iritis and general debility, even though there are no typical genito-urinary symptoms present.

How can this state of the gland be determined? First by palpation. Often the gland is firm, edematous, and enlarged. It may be of a hardness suggesting malignancy, or it may be soft and flabby. One must gently but thoroughly massage such a gland and catch the prostatic fluid expressed through the urethra. This should be examined microscopically for pus, red blood cells and bacteria. If the gland is under suspicion and one does not get an increase of pus cells, then a provocative injection of a mild silver nitrate solution should be made, and the massage repeated a couple of days later. One may then find an increase of pus cells with bacteria, which were absent at the first test. Sometimes repeated massage must be made to determine the extent of the infection present; most cases will show pus cells at the first examination, however. A clearing up of symptoms during treatment will show the probable causative relation between the two. It is surprising in many cases of this type of chronic prostatic infection how prompt and far-reaching may be the result of treatment. Patients who for years were unable to turn in bed or to stoop, will find prompt relief; patients who have been bedridden for months and even years, because of arthritic changes, may be made to walk and again become economically independent; patients mistakenly labeled as psycho-neurotics have been returned to useful, normal life by attention to a diseased chronic prostate. It is not our purpose to go into further details as to treatment, but only to call attention to such an entity of disease for which we should be on the lookout in any routine examination; on the other hand, we should not make a fetish of the prostate, nor ever neglect proper differential diagnosis.

---

*Read before the Southern Minnesota Medical Association, Mankato, Minnesota, August 25, 1930.

The other prostatic condition which should never be overlooked in a general examination, is that of hypertrophy or obstruction, whether due to adenoma, carcinoma, or an inflammatory condition. The examining finger in the rectum will often determine this, or a history of frequency, especially if nycturia is present, difficulty in voiding, and residual urine; 100 c.c. of residual urine is always an indication of a serious condition present, or threatening. One should differentiate the possible underlying causes, so as to institute proper treatment before serious vascular or renal damage is done.

Removal of the obstruction before serious damage is done, quickly returns a patient to a comfortable and useful life. Neglect of early diagnosis and proper treatment, on the other hand, is what develops morbidity and mortality. Residual urine is at once an indication for a blood chemistry to determine the functional capacity, or possible degenerative process going on in the kidneys.

Examination of eye-grounds for certain retinal vascular changes may reveal evidence of cardiovascular renal disease; a chemically normal urine, under such circumstances, would be suggestive of obstruction, rather than primary nephritis. The story is told of an oculist, who during routine examination of a patient's eye-grounds, made a diagnosis of hypertrophied prostate, the urine being practically normal to routine laboratory tests, but the characteristic retinal changes of renal degenerative damage being found. Looking into a patient's eyes and telling him he has a large prostate may be rather startling to the patient, and seem like a trick diagnosis, but can be explained by a logical sequence of physiological pathology.

If an obstructive condition is present in the bladder neck, one must determine the nature of the obstruction. This requires urethroscopy and cystoscopy. While this is in the province of the specialist, yet every practitioner should know of the methods required to arrive at a proper differential diagnosis in order to outline a method of procedure to the patient.

A patient of advanced age with nausea and vomiting may have uremia due to degenerative changes following bladder obstruction. Loss of weight and anemia may give the impression of gastric malignancy in this picture, and should be differentiated.

A cystogram often gives a clue as to bladder deformity or ureteral stasis and dilatation; a blood chemistry tells us how much retention there is of substances which should be eliminated normally; while the estimation of phenolsulphonephthalein gives a clue as to the renal capacity for excretion.

Thus early recognition of an enlarged obstructing prostate and prevention of infection of the bladder and secondary pyelonephritis with renal degeneration is worth while. It is more important to recognize the presence of a benign prostatic tumor than a malignant one, because there is a chance to help the patient with the former, and usually not with the latter case.

In conclusion, while it is not the purpose of this communication to go into detailed discussion of differential diagnosis, nor to discuss the treatment of these two conditions, namely, chronic prostatitis of non-venereal origin, and obstructing adenoma of the prostate, yet it is our wish to emphatically call attention to these two conditions in all routine examinations of adult male patients. Elaborate paraphernalia are not required, but a digital examination of the rectum can always be made and will rather frequently lead to an early diagnosis at a time when it will benefit the patient.

ACUTE DILATATION OF THE STOMACH*

James Morrow, M.D.
Austin, Minnesota

EVERY abdominal operation, and probably most other operations, where there has been either direct or indirect stimulation of visceral afferent nerves is followed by varying degrees of gastric relaxation. It is true of any condition, that the more we are interested in it, the more prone we are to recognize its beginnings and to become more watchful for its occurrence and its course. Gastric relaxation therefore may be present, but unless it should progress to a point of acute dilatation of the stomach, might not be recognized; but, the dilatation having occurred, a vivid picture presents itself. Yet no one cause alone will produce this picture; an anesthesia may or may not have been a predisposing cause: reflex stimulation may be aggravated by mechanical obstruction, and yet the risk is so great that we feel that it may well be worth while to consider this condition.

Two views are held as to the causation of acute dilatation of the stomach: either a marked inhibition of the vagus or an over-stimulation of the sympathetic, or strangulation or compression of the duodenum. The weight of both experimental and clinical evidence favors the first theory. It is not an uncommon occurrence to note relaxation of the gastric walls during the laparotomies when viscera are handled, such relaxation being due to a reflex nervous stimulation.

Experimentally, however, section of both vagus nerves above the diaphragm has not produced an acute dilatation with adverse symptoms, though relaxation of the stomach walls has occurred. The loss of tonus in the gastric musculature, regardless of its cause, will be the predominating factor. There is sufficient evidence to show that both ether and chloroform anesthesia reduce gastric tonus, and this must be considered as a contributing factor.

The question of an associated obstruction to the duodenum is distinctly a matter of controversy. It should be considered as a result of the dilatation and not a causative factor. Obstruction of the duodenum will not of itself produce an acutely dilated stomach. It is true that at postmortem examinations, in nearly every case of dilated stomach, some obstruction of the duodenum will be found. But careful examination will show that the degree is not sufficient to be a causative factor of the dilatation. For a very small degree of duodenal occlusion may produce a rapidly fatal toxemia; even an obstructive condition in the jejunum or ileum which will produce no symptoms, may, in the same degree in the duodenum, be fatal. This can be explained by the fact that the duodenum is capable of practically no distention and the fact that its nutrient vessels are arranged parallel to the long axis and that any degree of distention may result in an immediate circulatory damage.

The consensus of experimental and clinical evidence would therefore be that, in its etiology, an acute dilatation of the stomach would follow first a gastric relaxation and loss of tonus, reflex in origin, and that then a secondary mechanical occlusion of the duodenum follows either by direct pressure of the dilated stomach on the duodenum in its passage over the spine, or by an arterio-mesenteric compression brought about by the downward pressure of the dilated stomach. The important factor in the duodenal occlusion is the genesis of the toxic symptoms associated with this condition.

When the condition has actually developed, the symptoms are vividly present. As a rule, these symptoms do not present themselves till the third day, but even prior to then, certain consistent factors have been noticed which we feel are of importance. Even noticeable within twenty-four hours following operation, is the apprehension of the patient of a constant distress in the upper left quadrant. The pulse will increase even with a normal or subnormal temperature. There will be, with the use of enemata, passage of flatus from the bowel without relief of the upper abdominal distress. Examination at this time will show no fluctuation, but a marked tympanitic note may be observed over a large area of the upper abdomen. Passage of a stomach tube at this time will give immediate relief, and the striking fact is that this primary distention is due, not to any fluid content of the stomach, but is due entirely to distention with gas. Only mild, if any, toxic symptoms, are present. In most cases, with judicial after-treatment, no recurrence of the symptoms will occur. In cases when these first observations cannot be made, and in those cases which progress even after the above treatment has been instigated, the symptoms are an enormous accumulation of fluid in the stomach and the toxic phenomena of prostration, dehydration and collapse.

---

*Read before the Southern Minnesota Medical Association, Mankato, Minnesota, August 25, 1930.

The enormous amount of fluid which the stomach contains is the most apparent feature. This amount, in one of our cases, was nearly seventeen liters in a twenty-four-hour period. Nearly three liters were obtained at one time in another case. These amounts were far in excess of the fluid intake. This fluid has as a rule no sour odor, is fairly clear and usually has a yellow tinge. In only one of the cases, as tabulated later, was there any free hydrochloric acid present, but bile was present in every case, and fecal material present only in one case. Probably this fluid contains also duodenal secretions and pancreatic juices. It is hard to conceive that this enormous amount of fluid can be the normal output of the gastric glands, and must be the result of a profound stimulation, which stimulation comes probably from a chemical basis brought about by substances produced as secretive bodies from the duodenal mucosa. Such an amount of fluid entering the stomach naturally results in a generalized dehydration, evidenced by scanty urine of high specific gravity, albumin and later the appearance of granular casts, and the further symptom of extreme thirst that the patient presents. The pulse grows more thready and rapid, and the picture in the case progressing fatally is one of collapse. Such symptoms, together with the distended abdomen more marked on the left, the prompt relief of this distention following gastric lavage, leaves no doubt as to the diagnosis.

Only rarely can the diagnosis be confused. Peritonitis and postoperative ileus are the two conditions stimulated, but the lack of fever, the lack of a varying leukocytosis, the fact that in peritonitis the abdomen presents a more generalized tenderness and rigidity and is more diffusely distended, and the usual lack of fecal vomiting should rule out a peritonitis. Postoperative ileus usually involves the small bowel further down in its course, is not as early in its onset, and pain is a more prominent feature. Moreover, neither of these conditions responds immediately, as does a dilated stomach, to gastric lavage or to postural treatment.

The occurrence of an acutely dilated stomach in a definite form has been observed by us during the last few years in ten cases. These are tabulated below as an indication of the variations in which it has developed. A fact that has impressed itself on us is that in no case of operation on the stomach itself did there develop an acute dilatation.

Of the fatal cases, the first was a cesarean section performed for an eclampsia. The toxic symptoms were most marked, and were surely aggravated by the pre-existing eclampsia. Death occurred on the seventh day. Autopsy showed only an enormously dilated stomach filling nearly the entire abdomen (gastric lavage five hours prior to death), with a thin stomach wall. A definite angulation in the upper right quadrant gave the resemblance of duodenal occlusion, but this occlusion could very readily be overcome by the finger passing through the pylorus and duo-

GASTRIC DILATATION*

Case Number	Operation	Anesthetic	Onset	Bile	Free HCl	Fecal Vomiting	Albuminuria	Casts	Outcome
1	Inguinal hernia	local infiltration	60 hours	X	O	O	X	O	recovery
2	Appendectomy	ether	48 hours	X	O	O	X	X	recovery
3	Cesarean section	ether	72 hours	X	O	O	X	X	death
4	Tetanus	none	8 days	X	O	O	X	X	recovery
5	Cholecystectomy	ether	60 hours	X	O	O	X	O	recovery
6	Appendectomy	ether and gas	12 hours	X	O	O	X	O	recovery
7	Intestinal obstruction	ether	72 hours	X	3%	X	X	X	death
8	Fractured femur (plaster cast)	ether	12 hours	X	O	O	X	O	recovery
9	Hysterectomy	Spinocain	60 hours	X	O	O	X	O	recovery
10	Lipoma (thigh)	Novocain and sod. iso-amytal	7 hours	X	O	O	X	X	recovery

---

*Cases from records of Drs. Leck and Morrow.

denum. The case of intestinal obstruction which terminated fatally might be considered only as an obstruction were it not for the enormous amounts of fluids evacuated from the stomach. Unfortunately no autopsy was allowed.

I have referred at various times to gastric lavage. It is hard for me to mention acute dilatation of the stomach without a nearly coincidental thought of lavage, for of all the remedies proposed for the relief of this condition, it has been the only one consistently beneficial. And it is our impression that it is repeated lavage, at regular four-hour intervals, that is the deciding factor in the ultimate outcome. While I distinctly advocate lavage as the most important therapeutic method, it does not mean that additional methods should not be employed. The elevation of the pelvis to reduce the downward pull of the overloaded stomach; knee-chest position if practical; the use of small doses of surgical pituitrin—are all to be employed. In combating the toxemia, nothing is more beneficial than intravenous injections of 500 c.c. of a normal saline solution every four hours (our procedure is to give the saline after every lavage). Not only is the dehydration lessened by these intravenous injections, but blood chlorides are restored to the circulation, and a suppression of urine is guarded against.

The use of the duodenal tube in our experience has not been satisfactory. I think it probable that we do not get adequate duodenal drainage, because of the position of the stomach. Certainly there is not diminution in the toxic phenomena even though the duodenal tube is left in constantly, which shows that the toxic secretions are not withdrawn through the duodenal tube. Neither has the use of a small tube in the stomach, with constant syphonage, been as beneficial as active gastric lavage at regular intervals. While we have tried the procedure in only one case, there was absolutely no effect in relieving an acutely dilated stomach with the use of spinal anesthesia, though an intestinal non-mechanical obstruction can be frequently promptly relieved by this method. Surgery has no place in the relief of this condition, as a glance at mortality rates following surgical intervention will clearly show.

In conclusion, we may consider acute dilatation of the stomach an emergency condition demanding prompt and efficient treatment. Its occurrence may be anticipated at any time for it is not peculiar to any operation or to any anesthetic, and the reward of vigilance will be the lessening of what, up to recent years, has been an appalling mortality.

THYMOPHYSIN

Thymophysin is a foreign proprietary preparation of posterior pituitary and thymus claimed to be an oxytocic to accelerate normal delivery. In German periodicals, many articles have appeared praising the virtues of this mixture for use in the first and second stages of labor. Even in America a number of favorable but uncritical articles have been published. Erwin E. Nelson, of the University of Michigan, has reviewed the literature and carried out experimental investigations. He points out that the literature reveals no controlled evidence that the oxytocic or pressor activities of pituitary is altered by the addition of thymus extract. From his experimental work it appeared that, in this country at least, Thymophysin is incorrectly labeled as to its strength and no difference could be ascertained in the oxytocic or pressor activity of pituitary extract as compared with pituitary plus thymus extract. Nelson believes that the clinical results obtained from Thymophysin can be explained completely as due to small doses of pituitary extract. Thymophysin illustrates again the pitfalls awaiting those who are not thoroughly competent to undertake clinical evaluations but who arrive at conclusions based on the use of material the composition and activity of which have not first been scientifically determined. If physicians wish to undertake experimental clinical investigations with drugs, they will save time and protect the interest of the patient by limiting themselves to drugs whose chemistry and pharmacology have first been studied by the Council on Pharmacy and Chemistry. (Jour. A. M. A., January 31, 1931, p. 359.)

NON-MYXEDEMATOUS HYPOTHYROIDISM*

CHARLES N. HENSEL, M.D., F.A.C.P.
Saint Paul

TO those physicians living in the Great Lakes basin, diseases of the thyroid gland bulk large. That many individuals in this district suffer from an over-activity of the thyroid gland—hyperthyroidism—a voluminious literature and numerous "collar scars" amply testify. That there are many individuals in this district not obviously affected by under-activity of the thyroid gland—hypothyroidism—is not generally recognized. Unless an individual presents myxedematous changes in the skin and subcutaneous tissues with mental and physical torpor and increased body weight, hypothyroidism is seldom suspected. That there may be under-functioning of the thyroid gland without any of the above signs, will be a surprise to many physicians—because the belief still exists that under-functioning of the thyroid gland and the myxedematous syndrome are synonymous.

This is not strange when we realize how we have acquired our knowledge of myxedema. In the year 1875, Wm. Gull reported five cases, "characterized by swelling of the skin, and more or less complete apathy"—under the title "A cretinoid state supervening in the adult life of woman."

In 1877, Wm. Ord published six cases which he called "myxedema" on account of the edematous infiltration of the skin. In 1877—the same year—Charcot published similar cases which he designated as "cachexia pachydermique." In 1880, Savage reported on the first case of myxedema in the male. In 1880, Madden noted that in the myxedematous state atrophy of the thyroid gland was constantly present, but drew no deductions from this analogy.

About the same time, Kocher, of Berne, and Reverdin, of Geneva, independently reported on results following the total removal of the thyroid gland for goiter. They found a syndrome similar to that described by Gull and Ord, but surgically produced, and Kocher designated the condition, "cachexia strumiprevia." In 1884, an English commission appointed to study the etiology of myxedema, concluded that the only lesion constantly found in the disease was thyroid atrophy. "Without lesions or absence of the thyroid gland—no myxedema," said Kocher. Since that date myxedema and hypothyroidism have become synonymous and the belief is still general that you cannot have hypothyroidism without the myxedematous syndrome. But remember that myxedema is not a disease, but merely a sign in the skin and subcutaneous tissues as a result of hypothyroid function.

This sign was described in its relation to thyroid atrophy before we had any knowledge of direct or indirect metabolimetry. Since the perfection of indirect metabolimetry, hypothyroid states have been encountered as evidenced by reduced metabolic rates but without signs of myxedema.

At first physicians paid no attention to these low rates because no infiltration of the skin was present, but gradually it came to be recognized that, just as with kidney disease, there could be reduced kidney function without edema, so there could be thyroid disease—thyroid insufficiency without myxedema. Under this influence a budding literature is slowly growing up in which the condition under discussion is cautiously referred to as masked or occult hypothyroidism, mild hypothyroidism, small hypothyroidism, larval hypothyroidism, etc.

This caution obviously exists because the symptoms are largely subjective and the main reliance must be placed on the symptoms, plus lowered basal metabolic rates and response to thyroid opotherapy. These writers recognize the dangers of such types of diagnosis, especially in this day of ultra-scientific medicine when the clinical art ranks less than the laboratory science, in diagnosis and treatment.

Mention is made of hypopituitarism in which there is a somewhat lowered basal metabolic rate, asthenia, prolongation of the menstrual interval and sometimes urinary changes of hypo-suprarenalism with its intermittent asthenia, vasomotor instability, tremors, hypotension and failure to respond adequately to thyroid therapy.

If we can bear these two possibilities in mind and recall that they are relatively uncommon

---

*Read before the Southern Minnesota Medical Association, Mankato, August 25, 1930.

(about 15 per cent each, in a large series of cases), then we can keep our feet on the ground, tentatively diagnose non-myxedematous hypothyroid states from the symptoms, confirm the diagnosis by the reduced metabolism and clinch the diagnosis by the response to treatment.

Etiology.—Infections seem to play an important role. Roger and Garnier, in 1900, examined critically the thyroid gland in forty patients, dead of various infectious diseases, namely, measles, scarlet fever, diphtheria, small-pox, acute gastroenteritis, typhoid fever, cerebro-spinal meningitis and peritonitis. In nearly every case they found histological changes, such as diffuse hemorrhage, epithelial proliferation, swollen cellular protoplasm, poorly stained, cellular desquamation, with colloid thin or absent but very little change in the interstitial connective tissue. Quite obviously the infectious process had its chief effect on the secretive portion of the gland and their conclusions were that "infectious processes (after a period of functional stimulation leading to hyperthyroid symptoms) injured the thyroid gland and might eventually produce a more or less complete functional inhibition—hence hypothyroidism."

They postulate the fact that certain individuals have barely enough thyroid secretion to meet the ordinary physiological demands, but that as soon as their gland is overtaxed either through strain or by the toxins of infection, hypothyroidism develops.

Hypothyroid symptoms may occur at any time in life but are particularly common at certain ages and under certain conditions, namely, at puberty, at the menopause, during and following pregnancy, in the convalescent period following infectious diseases (notably influenza), and occasionally following extensive thyroidectomy for large degenerating adenomatous goiters.

Symptomatology.—The symptoms are bizarre. The chief outstanding complaint is fatigability, lack of "pep," no endurance, being tired all the time. These patients find it difficult to keep up with their daily tasks without becoming "all in." A night's sleep does not refresh them, they awaken tired in the morning, may work up towards a peak of energy sometime through the day, but this does not hold and their energy sags by night.

Some complain of daytime drowsiness; others, due to lack of energy, become mentally depressed. They suffer at times from severe headaches, hard to relieve by anything but rest, and are prone to generalized indefinite bodily aches and pains. Constipation may be extreme, menstruation may be excessive, and there may be lack of sex urge and sterility. Many note sensitiveness to cold, need extra bedclothes at night though they want plenty of fresh air in the room, want the temperature of the house 76 to 78 degrees and constantly have cold hands and feet.

None complain of dry skin or thinning of the hair; in fact in some of the most outstanding cases the skin is very fine, white and elastic. There is no constant physical type—all statures and body weights were represented. Out of fifty-six cases recently collected, twenty-four were of the lean slender type definitely below normal in weight, twenty-two were of normal weight and ten were over-weight. This point should be stressed, as the impression is current that hypothyroidism does not occur in thin people.

Physical Signs.—The general physical examination of these patients usually reveals very little. Many of them are alert mentally,—executives, salesmanagers, school teachers, students. Some show moderate swelling of the thyroid gland. In others a very small gland is just barely palpable or no gland at all can be felt. The pulse is usually slow (56 to 72), and the heart tones are frequently feeble or faint and distant with an occasional soft circumscribed systolic murmur over the apex.

Blood pressures are usually reduced from 116 systolic to 98 to 95 systolic, with diastolics between 80 and 60. Occasionally a patient will be below weight, show a swelling of the thyroid and have a tremor and an accelerated pulse, suggesting a possible hyperthyroidism. The blood may show a mild chlorotic anemia, but this is not at all characteristic. In fact, there are no symptoms entirely characteristic of hypothyroidism.

The one outstanding complaint is invariably undue fatigability. The one constant finding is a lowered metabolic rate. There is a wide range of variability in the degree of reduction of the metabolic rates, the readings ranging from minus 13 to minus 33 per cent, but showing no correlation between the degree of reduction and the intensity of the symptoms.

It was thought, following the postulates of Fahr in his cases of myxedema, which showed narrow Q.R.S. complexes and flattened T waves, that the electrocardiogram might serve as an additional differential diagnostic aid, but all my cases showed only the normal variants in cardiographic architecture, the Q.R.S. complexes being of good height and the T waves normal—occasionally high.

Differential Diagnosis.—When a patient complains of undue fatigability for months or years, headaches, generalized muscular pains, possibly constipation and susceptibility to cold, yet does not look particularly sick, is on a normal diet and yet does not gain weight but may even be thin, and on physical examination little else can be found but a slow pulse, low blood pressure, subnormal temperature and occult tuberculosis and cancer can be ruled out, and his basal metabolic rate is minus 10 per cent, or lower, and we can rule out hypopituitarism and hyposuprarenalism, then I think we are justified in making a diagnosis of non-myxedematous hypothyroidism and instituting treatment with thyroid gland substance or desiccated extract.

Treatment.—Treatment should be begun with small doses of thyroid gland to try out the patient's tolerance and to slowly raise the metabolism, remembering that the thyroid gland is a regulator of combustion in the body and with increased activity there is an increased combustion and possibly an accumulation of waste products faster than they can be eliminated. This may result in headache and general malaise. Also the thyroid increases the work of the heart more rapidly than its tone, so that sometimes pain and insufficiency develop. This is especially true if the patient is elderly.

If you use the dried fresh gland, the maintenance dose is on the average from three to five grains daily, while if you use the desiccated extract, the dosage is less, being one to two grains daily. Get to know one preparation and what it will do and stick to that brand and check the patient's metabolism at frequent intervals until you have found the proper maintenance dose that keeps him up to normal efficiency without producing symptoms of thyroidism. The thin hypothyroid will gain weight and the obese hypothyroid will lose weight, owing to the tendency of normal thyroid secretion to normalize metabolism.

At times it seems that following an acute respiratory infection such as bronchitis or influenza or tonsillitis, the hypothyroid patient on thyroid therapy may not show a normal convalescence, but may exhibit again signs of his original hypothyroid state to a moderate degree. Recheck of his metabolic rate will show an additional drop which necessitates, for the time being, an increased dosage of thyroid extract.

Therefore, it is important to watch these patients and check their metabolic rates from time to time. An occasional patient seems to have a regeneration of the thyroid gland under treatment and, ultimately, substitution therapy must be discontinued—otherwise thyroidism results. I have seen a female hypothyroid patient slightly overweight, in order to lose more weight, greatly increase on occasion the prescribed dose, of her own accord, producing thyroidism, namely, loss of weight, palpitation, nervousness, and insomnia. These symptoms have invariably subsided on the withdrawal of the drug, with no evidences of permanent constitutional damage.

I have watched all my patients on thyroid medication very carefully and so far have not had one develop goiter or signs of toxicity other than the one case above described.

MEDICAL PIONEERS OF MINNESOTA*

William J. Mayo, M.D.
Rochester, Minnesota

DR. GEORGE E. DE SCHWEINITZ, the dean of American ophthalmologists, who was president of the American Medical Association in 1922-23, speaking of the advice which should be given to a young man starting out in life, said, "When I went away to college, my father saw me off at the train and said to me, 'George, I am not going to give you a lot of advice, but I want you to remember that you come from respectable people.'" The more one thinks about this brief counsel relative to the forming of character, the more one is impressed with its true significance.

We, who are here today, must be impressed with the fact that we are members of a respectable profession, made respectable by the pioneer physicians who have gone on before. In the early days medical men of courage and vision came to Minnesota with other valiant pioneers, to face the hardships of frontier life. The great test of courage in those who preceded us in Minnesota was contact with the most intelligent, the most courageous and the most warlike of the American Indians, the Sioux. Who here has not read the Leather Stocking Tales of Fenimore Cooper: The Last of the Mohicans, The Deerslayer, The Pathfinder? As a boy I always pictured these romantic stories in relation to the Minnesota Valley.

My father came to Minnesota in 1854. He was the medical officer with the Territorial Survey which laid out the northern counties of the state. When St. Louis County was surveyed, there were few inhabitants in that vast territory. At Rice Point, near where Duluth now stands, there was one cabin, but the trapper who lived there was away, and therefore Father was made temporary chairman of the first board of county commissioners, an office which he held for about six weeks, until someone who lived in the county could be found to take his place. In 1856 Father moved to Le Sueur, on the Minnesota River, the head of navigation, to practice his profession. At that time one little boat plied irregularly up and down between Le Sueur and St. Paul. When the Civil War broke out, Father was one of the United States Medical Examiners, and in 1862, when the great Indian outbreak took place, he was with the small detachment of soldiers and men who went to New Ulm to repel the Indians. They told the story afterward that during the siege Father had just completed an amputation of a leg for gangrene, when, looking out of the improvised operating room, he saw two of the undisciplined guards, who had been instructed to remain at a post of observation, sneaking back into the settlement. He started after them with the long amputating knife used in the early days, and turned them back to the line of duty.

With the men at the front, and only women and children left in Le Sueur, my mother organized the women to represent a company of soldiers. She dressed them in men's clothing and armed them with pitchforks, and fence pickets to the top of which knives, forks, spoons or bits of tin had been fastened, which would glitter in the light and look like bayonets, and several times a day marched them in military formation about the settlement. The Indians, who were massacring settlers in every direction, seeing Le Sueur from the hills, believed that soldiers had come up on the boat as a guard, and did not attack.

At the close of the Indian uprising, when thirty-nine Indians were hung at Mankato, Father secured the body of Cut Nose, a huge Indian who, in some predatory expedition, had received a cut with a tomahawk through the edge of the forehead and face which almost severed the nose. Father cleaned and articulated the skeleton, and on this skeleton, under his instruction, my brother and I, as small boys, learned our osteology.

Early in 1863 Father was sent to Rochester as United States Medical Provost-marshal to entrain troops. The railroad had just come to that vicinity.

I mention these incidents because of the influence that they had on my brother and me in fixing the Minnesota Valley in our youthful minds as a field of romantic adventure, and the romance of those early years remains with us to this day.

---

*Talk before the banquet of the Southern Minnesota Medical Association, Mankato, Minnesota, August 25, 1930.

The Minnesota State Medical Association was organized in 1869. My father was one of the founders and its third president. The Minnesota Valley Medical Association, which was next in size, was organized December 1, 1880, at Le Sueur. In the previous October a number of physicians of Le Sueur County had met at Le Sueur Center and had partially organized a medical association and named it the Minnesota Valley Medical Association. Dr. Otis Ayer, Le Sueur; Dr. C. F. Warner, Mankato; Dr. A. W. Daniels, St. Peter; Dr. Alfred Muller, New Ulm; Dr. G. F. Merritt, St. Peter; Dr. Z. G. Harrington and Dr. E. J. Davis, Mankato, with others, were members of this group.

Even while I was a student of medicine, I had the opportunity to attend with my father several meetings of the Minnesota Valley Medical Association, which were held yearly in Mankato, and there I had the privilege of seeing some of the medical pioneers. One of them in particular I can still see in my mental vision, Dr. Daniels of St. Peter, a cultured gentleman. It was inspiring to see a man of that type in pioneer surroundings. When on one occasion Dr. Daniels saw me at the meeting of the society with my father, he said, "So you are going to study medicine? Well, it is the most satisfactory of all the professions. It is doing for others. I have always been physically very well, and let me advise you that when you go into the practice of medicine and begin to go about the country seeing patients, be careful what you eat. I have found it wise to ask for a boiled egg, a baked potato, hot toast, and to drink tea or coffee, something that has been boiled and is still hot." Thus I learned from an observant man the knowledge that unclean food might be the cause of much sickness.

Dr. Alexander Stone, of St. Paul, was one of the finest speakers in the medical profession of the state of his time. Dr. Charles T. Wheaton, the surgical hero of my young professional life, a graduate of Harvard who had interned at the Boston City Hospital, was a very fine anatomist and a conscientious and most courageous surgeon.

Dr. James Dunn, of Shakopee, later of Minneapolis, and Professor of Surgery at the University of Minnesota, was the most learned surgeon of his time in the Northwest, I believe. He had spent two years in Germany. He used to come down to see us at Rochester, and he was always cold. We would always build a fire in the grate, and he would drop into a chair in front of the fire, resting apparently on the back of his neck, stretch out his long, thin legs to the blaze, and become reminiscent. On one of his trips back from New York, he stopped with us for a few days, as he often did. I was very much interested to know what of interest he had seen on his visit, and asked him. He said he had seen many things. "The funny thing about it is that when I get off and see things, I make up my mind that I am going to do them, and when I come home, I find myself sliding back into the old ways I have always used and have confidence in." He went on to say, "My wife and I go every year to New Hampshire to a lake where a farmer has some cottages. When we were younger, we enjoyed the rough living, but as we have grown older and more sophisticated, we should like more conveniences. We and some of the others who go to the lake regularly decided to take up a collection and send the old man away to see resorts elsewhere. We did not want to ask him to make changes for our benefit, but we thought if he saw what other places were doing, he would want to do the same. When he returned from his trip, we all met him at the boat. He got off full of enthusiasm. 'Boys, I have seen them all, Newport, Atlantic City, and, do you know, this is the only place they have seven different kinds of pie for breakfast?' "

I remember well Dr. N. S. Teft of Plainview, with dangling lower extremities, crippled by infantile paralysis, carrying his heavy body around on crutches, doing country practice. Nothing was allowed to interfere with his work. He would start off through the snow in winter, and if he did not return at a certain time the livery man would take a team and go to find him. Perhaps he would be in a snow drift; hardly able to blanket his horse, and waiting down under the robes for rescue.

The Southern Minnesota Medical Association was organized July 28, 1892, with a membership largely from the southeastern part of the state. Of the leaders in this group, I remember Dr. Franklin Staples and Dr. J. B. McGaughey of Winona, Dr. Charles Hill of Pine Island. Drs.

W. H. Lincoln and W. F. Milligan of Wabasha, and Drs. E. C. and E. W. Cross and W. W. Mayo of Rochester.

It was decided after many years of success that the Southern Minnesota Medical Association and the Minnesota Valley Medical Association should combine in order to extend the membership into the southwestern part of the state. This was done willingly, but nevertheless with great sorrow by the old pioneers of the Minnesota Valley Association.

It is to these pioneers that we owe the splendid position the Minnesota medical profession now occupies. Early in the 80's an enactment was brought through the Legislature which did much to keep out medical chaff from Minnesota. This law was fairly well enforced and has been improved on at various times, until today the Basic Science Act does much without prejudice to keep the profession of the state clean.

The pioneer medical profession of Minnesota, part and parcel, exemplified character and courage. Especially let me dwell on courage. Minnesota in three great wars, the Civil War, the Spanish-American War, and the Great War, organized and sent to Washington the first volunteer regiment and in each and all of these wars sent a larger percentage of volunteers in proportion to the population than any other state in the union.

Let us rise for a moment in silent homage to the medical pioneers who have made Minnesota so respectable a place in which to practice medicine.

RENTON'S HYDROCIN TABLETS

Under the name "Renton's Rheumatic Tablets" the Renton Company of Pasadena, California, put out an alleged rheumatism cure a year or so ago, under the claim: "What insulin is doing for diabetes, Renton's Rheumatic Tablets are doing for arthritis, neuritis and rheumatism." After the preparation had been on the market for some time, the officials at Washington in charge of the enforcement of the Food and Drugs Act are said to have made the Renton Company elimiinate the word "Rheumatic" from their labels and the nostrum became "Renton's Hydrocin Tablets." The A. M. A. Chemical Laboratory, reports that each Renton's Rheumatic Tablet was found to contain essentially 0.32 Gm. (approximately 5 grains) of cinchopen, with a relatively small amount of an unidentified amine. The Laboratory reports that qualitative tests indicated Renton's Hydrocin Tablets to contain the same ingredients as found in Renton's Rheumatic Tablets, and that the amino compound present was identified as a tetra-ethyl ammonium compound. Although the tablets were stated to be enteric coated, the Laboratory found that the coating flaked off when they were immersed in 0.2 per cent hydrochloric acid. Summed up, it appears that people who pay $1.50 for fifty Renton's Hydrocin Tablets are getting what is essentially fifty five-grain cinchopen tablets, which could be purchased at almost any drug store at half the price, and, what is of more importance, with the possibility of the dangers and limitations of the drug known. With the increasing number of cases of acute yellow atrophy of the liver following the continued use of cinchophen it seems little less than criminal that irresponsible "patent medicine" exploiters should continue to put this potent drug into their secret mixtures, with no warning as to the possible dangers in its continued use. Nor are the large and supposedly respectable pharmaceutical houses, which put up such formulas for "patent medicine" manufacturers, free from moral responsibility. (Jour. A. M. A., January 17, 1931, p. 209.)

THE ART OF MEDICINE*

Walter C. Alvarez, M.D.
Rochester, Minnesota

LOOKING back over the years can you not, every one of you here tonight, remember some of your classmates in college who were good students and who could turn in excellent examination papers but who, when they went out to practice, somehow or other failed to achieve what is commonly known as success. You will remember also some very poor students who perhaps flunked out and later succeeded in getting through a diploma mill and somehow past a state board and who are now staggering under the burden of an enormous practice.

Now it is true that some of the men who could not or would not study at college did buckle down when brought face to face with the needs of their patients, and they did learn something about the science of medicine and surgery, but this is not the explanation for the success of many of the others. I have met some of them in consultation and have always come away wondering how anyone could have been "exposed" to so large a mass of clinical material without learning something from it about the nature of disease. I remember once going with one of these men into a room where I needed but one look to tell me that the fat cyanotic ex-brewer who lay propped up in bed was in the last stages of terminal pneumonia. When I stepped into the next room and told my colleague what he was up against I was astounded to find that he hadn't even suspected that the lungs might be involved. In order to get a diagnosis he had sent some urine and blood to a commercial laboratory, and when the report came back that the man had nephritis, well, nephritis it was until the family became alarmed enough to ask for a consultation.

A remarkable practitioner.—I have often tried to analyze the reasons for the success of the most remarkable of all these poorly educated physicians whom I have known, a man who, while working some forty years ago as a barber, went for a few months to a third rate college and there attended some lectures. With this excellent scientific foundation, he hung out his shingle, and from then onward until a few years ago, when a stroke ended his career, he enjoyed what was probably the largest and most lucrative practice to be had in a certain large city of this land. The estate which he left was appraised, if I remember correctly, at well over a million dollars. I have several times met this man in consultation, and always on such occasions I have been surprised at his inability to read some of the plainest sign-posts of disease. Surely his success was not due to any skill in diagnosis. Well then, to what was it due? Most of you will doubtless expect me to say that it was due to the fact that he was a big, fine-looking, magnetic sort of man, well endowed with all that personal charm and that appearance of distinction which gives to certain men the prestige and power to command their fellows, to lead them, to influence them, and even to heal them.

No, that was not it. He was an insignificant looking little man, barely five feet tall, and quite devoid of any charm of manner that I could detect. So far as I could see his success was due largely to three factors: first, his clever use of consultants to make his diagnoses and to shoulder responsibility when things went wrong; second, an ability to work hard twenty hours out of the twenty-four; and third, and I think most important of all, a canny knowledge of human nature and of much of the art of medicine.

I have often wished that some of my younger confreres in the medical profession, those who by refusing to accept consultations insist on keeping for themselves all the obloquy that can come from the loss by death of a prominent patient, could learn the lesson that this man might have taught them. Always, whenever he was concerned about a patient or whenever he sensed the least anxiety on the part of this patient or of his family he would immediately call in one or more, commonly more, of the best consultants he could get. The patient was usually much pleased over these signs of his own importance, the family was reassured and given much to brag about, and if later anything went wrong, it never occurred to them to lay the blame on their beloved family doctor.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota. Read before the Southern Minnesota Medical Association, Mankato, August 25, 1930.

Once the diagnosis was made and the treatment outlined, this wise old practitioner devoted himself to the task of making the patient comfortable. In this he spared no pains, and if the illness was severe and the family of the patient anxious he made at least three visits during the course of the day, the last one often on tip-toes at two in the morning. Good nurses were secured and no stone was left unturned to make the relatives feel that everything possible was being done.

It was remarkable, moreover, that with all his enormous practice, keeping two chauffeurs going from six o'clock in the morning to two or three o'clock the next morning, he often found time to call socially on his old patients. If for any reason there was rejoicing in a home—the promotion of a son to new honors, or the wedding of a daughter—he would drop in for a few minutes to hear about the details and to express his pleasure. He was, therefore, not only physician to hundreds of families but he was counselor and friend.

With the help of a few gossipy old ladies he kept in touch with everything that was happening among his clientele and he promptly responded to anything that might affect his interests. In his later years, when some of his younger patients began to recognize his scientific limitations and began to look elsewhere for medical advice, they had great difficulty in breaking away. When they consulted other physicians they did it furtively, not only because they hated to hurt their old friend, but because they did not dare to admit their defection to a mother or grandmother still much devoted to him. His was, I think, the most extreme example I have known, of a man who, without prestige of birth or breeding or education or physique, turned to tremendous account a knowledge of human nature and of the art of medicine.

The need for art.—Now I have not been telling you so much of this man's life and skill because I think it is so admirable or because I think a huge practice is to be desired above all things. Fortunate it is that there are many men in our profession who would refuse to give up everything worth while in life to the demands of such an inexorable treadmill. The reason why I have spent so much time talking about this man is that I could not think of a better way in which to emphasize the importance to us all of the art of medicine. Surely if a man without any scientific training could, through art alone, walk off with the best practice in a large community, what might not those of us who possess some scientific skill do if in addition to this we were to develop a finer art. This art we must try to learn, not for any selfish reasons, not with the idea only of increasing our incomes, but with the idea of giving better service to our fellow men. One of the saddest thoughts that must daily come to the sanitarian is that in this modern world there are hundreds of thousands of men and women who, when ill, refuse to accept the help which modern scientific medicine and surgery could easily give them. Often as one talks to these persons one finds that their refusal to have anything more to do with the medical profession is due to the fact that once upon a time they or their relatives were much upset by the doings of some tactless or unfriendly physician.

Furthermore, what is the use of spending ten or twelve years and thousands of dollars in giving a young man a fine training in the science of medicine if when he goes out in the world his lack of knowledge of the art is going to make it impossible for him to get a practice and to use his science. A few years ago I happened to be where I could watch the career of a young man whose knowledge in a certain field of medicine was encyclopedic. His brilliant writings soon caused many patients to seek him out but somehow or other he never seemed to learn the rudiment of tact, of savoir-faire, or of medical art; those who consulted him soon left disgruntled, and as a result he took down his shingle, and became a full-time professor in a medical school!

All of which leads me to another thought which is that today medical students, even in our best colleges, are being more and more poorly trained in this art that I am talking about. The younger generation of medical teachers today are mainly interested in the biochemistry of serious disease; more and more of them are stepping directly from the laboratory into the professorial chair, and as a result there will be fewer and fewer with any knowledge of medicine as it is practiced in a downtown office, with patients from the middle and upper classes.

Fortunately, those at the head of some of the leading schools in the country are now beginning to see the great need for correcting this defect and with good sense they are turning for help to the outstanding practitioners in their respective states, asking them either to give lectures or to act as preceptors so that the students can learn something about medical practice as it is actually being carried on out in the world. Unless this sort of thing is done, every year more and more students are going to graduate from even our best universities well equipped with information about the rarer diseases, which they will seldom encounter, and woefully unprepared to deal with the functional troubles which they will see several times a day. They will have learned much of the science of medicine but little if anything of the art.

What is this art?—But what is this art that I am now supposed to talk about? I should say that it is the knack of dealing with the patient in such a way as to gain his confidence, his respect, and his liking; it is the knack of inspiring him with the feeling that here at last is a man who understands his case and will cure him; it is the knack of keeping this trust even when things go wrong, when health and comfort do not return, and when, perhaps, as is the case with many illnesses, things continue to go from bad to worse; and it is the knack of making the patient comfortable and of adjusting the prescribed treatment to his particular idiosyncrasies of mind and body.

Can this art be learned?—Yes, most of it depends first on having a thorough knowledge of disease and this must be learned from books, or, better yet, from a careful study of patients; much of it can and must be learned by making mistakes and by profiting by them; some can be learned from teachers, but the ability to learn the art and to practice it depends largely on the student's original endowment of brain and heart, on his ability to like people, to get on with them, to understand them, to sympathize with them, and to be kindly with them. In other words, the ideal physician must be born. Probably in no other calling is there more need for good judgment, for good sense, and for the equanimity and poise and culture and charity of a philosopher.

The ideal physician can I think be fashioned most easily out of the type of man whom one commonly finds serving as the balance wheel of a large family: the relative to whom they all turn for help and advice in time of trouble. Such men often possess a certain dignity and personal prestige that make it easy for them to lead and to command their fellows. Fortunate are they who have it, because daily they must give orders, often to those who are not accustomed to receive them, and daily they must give freely of their strength and vitality and hopefulness to those who are weak and frightened and discouraged.

Some physicians fail to obtain the type of practice which their scientific skill should have brought them because they are careless about their personal appearance. Others expect well-to-do patients to come hopefully to a dingy office, which looks antiquated and down-at-the-heel. They forget or perhaps never knew that in ages past medicine was practiced successfully with the help of the prestige that came from beautiful temples and an impressive ritual. Even today the prestige that comes from a tastefully but not too elaborately decorated suite of offices filled with well dressed patients is not to be despised.

Taking the history.—There is an art in putting the patient at ease when he or she first comes in, nervous and frightened, and perhaps ready for flight. Often the physician will do well to spend the first few minutes talking about some non-medical topic: one brought to mind perhaps by noting the name of the town from which the patient comes or the name of the friend or physician who referred him. With certain patients it is helpful to establish in this way some friendly contact before starting the quiz on medical matters.

The taking of a good history, which brings into play every bit of scientific knowledge which the physician has, will at the same time call upon him for the exercise of all his skill in the art. The taking of this history and the making of a thorough physical, roentgenologic, and laboratory examination constitutes the first and most important step in the psychic treatment of a nervous and worried patient. Unless the physician takes such a history—one which brings out the details of family and business worries, of domestic infelicity, or of phobias—he cannot expect to work a cure. Unless he obtains this information the patient will go away dissatisfied because, although he does not admit it, he knows in his heart that the real cause of his trouble has not been touched.

Many patients conceal the most important facts about their troubles. They will not volunteer the information that someone has recently diagnosed cancer or syphilis, and they will even deny the fact that at home there is bickering, unhappiness, and thought of divorce. A beautiful young Italian woman who came to The Mayo Clinic recently from Chicago complaining of constant headaches maintained stoutly that her home life was happy and that she had no worries. Only from a friend was I able to learn what I suspected; namely, that her husband was in the liquor racket and that she was living in hourly dread of his assassination.

Obviously a physician who is to practice the art of medicine must learn when to suspect that these important factors are present, and he must become skillful in making the reticent patient confess. I often do it by telling a story similar to the one I expect to get. The physician must also have a sixth sense to tell him when the patient is lying and he must watch keenly for telltale signs of emotion or hesitation as answers are being made to certain questions. Time and again I have been led directly to the cause of a neurosis by noting on a woman's face signs of pain as some question was answered, or by seeing her shoot a meaning glance at her husband.

After a long history has been written down it takes perhaps as much art as science to decide what is important and what is not. This is shown so clearly in those cases in which, after having been called for twenty years a "pure neuro," a woman is found to have a gallbladder full of stones. Often then, if the physician will go back over the history, knowing at last what is relevant and what irrelevant, he can pick out here and there symptoms which, when pieced together, tell the typical story of cholecystitis.

What to say and not to say.—The greatest need for art in medicine comes when one begins to talk to the patient about diagnosis and treatment. In many cases, of course, the problem is simple; the patient is intelligent, willing to accept what he is told, and willing to coöperate. The diagnosis is clear and there is little doubt as to what should be done. But in many of the cases seen in modern consultant practice the problem is very difficult. The patient, commonly a woman, perhaps psychopathic, suspicious, overly sensitive, spoiled, and somewhat of a tartar to begin with, has traveled so much, has been told so many conflicting things, and has suffered so much at the hands of so many physicians that it is small wonder that when she goes to a new one she is on her guard, diffident, critical, and hard to influence.

In such cases the physician who is to succeed must, as he talks, watch the patient's face closely in the hope of sensing when he is saying the right thing and when the wrong. He must watch for every sign of emotion, interest, acquiescence, unbelief, antagonism, or annoyance that flits across the face of the person before him. If he sees that inadvertently he has given alarm, he must stop and reassure; if he has preached a little too pointedly and has caused resentment he must stop, to soften his words and to express sympathy; if he has failed to make things clear he must try again with simpler speech; if he is antagonizing the patient he must know it and must try another tack; or if the patient is becoming fatigued he must terminate the interview.

Although the importance of feeling one's way is perhaps greatest when one is talking to the patient in whom nothing organic has been found to explain the presence of trying symptoms, it may be great also even when the diagnosis is definite and positive. With certain patients it is no easy task to give a clear and impressive idea of the seriousness of the disorder and the need for prompt and thorough treatment without at the same time producing such alarm and resentment and unbelief that the patient will promptly leave to consult someone else. One of the worst things we physicians often do is to give from the start a hopeless prognosis. It rarely is necessary to do this; it is almost certain to destroy our further usefulness to the patient or his family; often we are wrong, and whether right or wrong, we will often lose the good will of a whole family.

We all know, also, the type of physician who when he sees what he thinks is organic abdominal disease will try immediately to rush the patient into the hospital for an emergency operation. Sometimes this maneuver works but often it does not, and then the physician is left to contemplate the fact that if he had had more art and more knowledge of human nature he would have seen in time that this particular patient could only be scared away by such tactics. I have often been told by patients that they would long before have accepted a needed operation if only the surgeon had taken the time and pains to explain in ordinary speech what he wished to do and why. Time and again I have seen Christian Scientists and other such persons who had sworn never to consent to an operation go cheerfully to the hospital after the mechanical nature of the problem involved had been explained to them, and after ample time had been given them in which to change their minds. In such cases I do not urge operation but explain the need for it and then let the idea work in gradually.

When one is talking to patients about certain serious and commonly fatal diseases there is an art also in avoiding the use of those words which are so closely bound up in their minds with the idea of hopeless suffering and death that they cannot bear to hear them used, especially when their hearts are full of anxiety and fear. I refer particularly to such words as cancer, epilepsy, Bright's disease, and consumption. If you wish to earn the undying gratitude of the harrowed and grief-stricken mother of an epileptic child, use if you will such terms as petit mal or "syndrome of meningitic irritation" or seizures, but never that dread word which will cut into her heart and brain like a knife. These may seem to be little things but many a time I have seen a patient change physicians on account of them.

One of the most devoted and grateful patients that I ever had was a man with an inoperable carcinoma of the stomach whom I tried to make fairly comfortable during the last few months of his life. I learned from his wife that they had left another physician because this man insisted on talking about cancer. The patient, like so many others with this disease, had metaphorically buried his head in the sand; like Moran of the Two Black Crows, he "didn't want to hear no more about it," and he was grateful to me because I treated him without ever a word about diagnosis or prognosis.

And this brings up the difficult problem of knowing how truthful to be with patients. Here again we often have need for all the art that we can summon to our help. If a man looks me in the eye and says, "What is the trouble?" I believe it is my moral and legal duty to tell him what it is even if it is inoperable caancer. But if, knowing in his heart what he has, or having been told by someone else, he comes at the instigation of his family and does not ask me any questions, what right have I to sear into his soul with terrible words? Often, also, when a patient is trying to find out if his albuminuria means Bright's disease the wise physician will refuse to use this dread term, because he knows that, once he has done so, no amount of explaining will ever put across the idea that the lesion is probably dormant, that it is little more than an old scar, and that there is nothing to indicate that life will be shortened.

Perhaps most important of all, if the physician does not know what is wrong it is not his duty to poison the patient's mind by telling him that his symptoms are suggestive of such diseases as brain tumor, multiple sclerosis, locomotor ataxia, or pernicious anemia. Similarly if the first Wassermann report is one plus, it is not fair to tell the patient of this and perhaps to make of him or her an incurable syphilophobe. Why not wait a day or two to see if the next two reports will not come back marked negative? In other words, the wise physician who practices the art of medicine does not tell all he knows; he carries in his heart a large share of the burden of worry, and by so doing spares the patient much anxiety and himself much unnecessary argument.

The greatest need for careful speech comes often when one has to tell a seriously incapacitated patient that the complete examination has failed to reveal signs of organic disease. Here the physician needs all the tact, sympathy, and kindness that he can summon to his help. After reviewing the record and explaining that nothing has been found that would justify surgical intervention, I think it well to admit that, although this should occasion considerable rejoicing, it also has its disappointing side. I try to assure the patient of my confidence in the existence of his symptoms, and I remind him that many bodily functions can be upset in sensitive persons by strong emotion, worry, and fatigue.

If the patient has been overworking and losing a great deal of sleep, I picture to him thousands of delicate brain cells crying out for rest; I suggest that he give heed to their complaint, that he cut down on work, try a simpler diet and better methods of regulating the bowels, and see what happens. If everything clears up, we shall be happy; if some of the symptoms disappear and others remain or if new ones appear and others get worse, the correct diagnosis may either become obvious or another careful examination may show what is wrong. One great advantage of this method is that I have not burned my bridges behind me. If things go wrong, if new symptoms develop and the diagnosis becomes obvious even to a tyro in medicine, I shall not be humiliated by having my mistake corrected, perhaps by some unfriendly critic, and I shall not have earned the contempt and enmity of the patient and his family.

I could go on perhaps for hours telling you about the art of adjusting a diet to the needs of a fussy patient, the art of making certain persons eat more, the art of carrying out a successful rest cure, or the art of conducting a satisfactory consultation, but I think I have already made my point, which is that a knowledge of the art of medicine can greatly extend the usefulness of every skilful and scientific physician in the community; it will enable him to render better service to a greater number, and it will bring greater peace of mind and hope and comfort to his patients.

MISLEADING METHYL CHLORIDE PUBLICITY

The Committee on Poisonous Gases of the American Medical Association issued a report emphasizing the hazard arising from the use of methyl chloride in refrigerators. In the view of the committee it is more commendable to work toward the attainment of a nonhazardous refrigerant than toward the attainment of a usable warning agent. Nevertheless, chemical manufacturers have apparently been able to induce the Bureau of Mines to make studies of the properties of methyl chloride and methyl chloride to which has been added acrolein, an irritating warning agent. One of these concerns, the Roessler & Hasslacher Co., markets methyl chloride under the trade name of "Arctic" and Methyl Chloride A, which is pure "Arctic" plus 1 per cent of acrolein. A report of the Bureau of Mines appeared which was written in such a way as to lend itself to use as advertising copy by writers seeking to create favorable propaganda for commercial exploitation of methyl chloride. The report emphasized that methyl chloride exerts no deleterious effects on the contents of the refrigerator and implied that it is therefore of no importance whether or not methyl chloride escapes into the refrigerator. The major point—the hazard of escaping methyl chloride to occupants near the source of the leak—is not stressed. The Roessler & Hasslacher Chemical Company has used the report to create the impression that "Arctic" is a relatively harmless substance and the last word in efficient and safe refrigerants. It is unfortunate that a branch of the government, the Bureau of Mines, has been swayed to serve more the interests of chemical manufacturers than to serve the interests of the public. (Jour. A. M. A., January 24, 1931, p. 272.)

TREATMENT OF COUGH AFTER BRONCHITIS

Children who cough should not be permitted to attend school. If the child has fever, it should be kept in bed. Warmth, as uniform as possible, is the prime requisite in the treatment of colds and acute coughs. The chief of all expectorants is water: without it most medicinal expectorants fail and, with an abundance of it, they may not be required. Nevertheless, they probably contribute, when wisely used, to a speedier evolution of the various stages of bronchitis and to a more rapid recovery. The salines, chief among them ammonium chloride and sodium citrate, head the list of agents that may reasonably be expected to be of use in "loosening up" a cough, provided they are given freely, frequently and with plenty of fluid. Iodid, the most powerful of the saline expectorants, should not be employed until the acute stage is well over. When the cough is "loose," aromatics may be of value such as terpin hydrate and creosote. A cough that hangs on is not so much an indication for medicine as a challenge to determine why it does. (Jour. A. M. A., January 3, 1931, p. 61.)

ANTITOXINS AGAINST SCARLET FEVER

No "one-shot" method of active immunization against scarlet fever has proved effective. The present status of the "ricinoleated antigens" is that they are of unestablished value. Their therapeutic action has not been proved. Scarlet fever ricinoleated antigen has been distributed by only one concern and that concern has recently discontinued the manufacture and distribution of ricinoleated antigen and is recalling it from the market. (Jour. A. M. A., January 24, 1931, p. 292.)

FIBROSARCOMA OF A MECKEL'S DIVERTICULUM PRODUCING INTESTINAL HEMORRHAGE*

Louis S. Faust, M.D., and Waltman Walters, M.D.
Rochester, Minnesota

MECKEL'S diverticulum is found in from 2 to 3 per cent of the population, according to necropsy records, and, as is commonly known, is due to failure of the vitelline or omphalomesenteric duct with its accompanying vessels to become completely obliterated. It usually arises from the ileum about 90 cm. from the illeocecal valve, although rarely it may be found anywhere in the gastro-intestinal tract from the cardia to the rectum. It varies in size, from 2.5 to 10 cm. in length. Ordinarily the diverticulum is found on the antimesenteric border of the ileum but it may exist at any point on the circumference of the ileum and rarely between the leaves of the mesentery. Under the latter conditions, when it is of sufficient length, it may resemble an intestinal duplication. The vessels accompanying the vitelline duct may fail to become completely obliterated; they may persist as fibrous cords, and are found either hanging free from the tip of the diverticulum or attached to the abdominal wall at or near the navel or to the mesentery. The point of attachment of these congenital bands in the abdominal cavity is variable. These bands are important sources of intestinal obstruction and strangulation, as has been so clearly shown by Fitz. At times a separate mesentery is found connected with the diverticulum. Schaetz demonstrated gastric epithelium in Meckel's diverticula and has shown that this aberrant gastric mucosa may be the seat of ulceration similar to peptic ulcer.

That ulceration in a Meckel's diverticulum may result in massive intestinal hemorrhages with severe secondary anemia has been noted by a number of observers.[1, 10, 12, 13, 15, 18] From a survey of the literature, it would seem that most cases occur in infants or children. As in the duodenum or stomach, these ulcers may give rise to hemorrhage or perforation. Inflammatory changes not infrequently occur in the diverticulum.

Coley and others reported tuberculous ulceration of a Meckel's diverticulum and mentioned that typhoid perforation has occurred.

Invagination of Meckel's diverticulum with formation of intussusception may occur. Hertzler and Gibson, Shannon, and others reported such cases. Deformities about the umbilicus should suggest the presence of a persistent vitelline duct. Usually the distal end of the diverticulum closes but it occasionally remains open, forming an umbilical fecal fistula. A prominent reddened tumor called an omphalo-adenoma occasionally may be seen when only the umbilical portion of the vitelline duct remains.[3, 7] The diverticulum may be the sole occupant of a hernial sac.[3]

There is nothing distinctive or pathognomonic in the clinical features of the various pathologic changes which occur in Meckel's diverticulum. The fact that this product of faulty development is present in from 2 to 3 per cent of persons and may produce clinical signs of intestinal obstruction, perforation or hemorrhage, alone or in combination, should be emphasized. The symptoms may simulate those of appendicitis or intestinal obstruction. Since the lesion is small, roentgenologic examination of the gastro-intestinal tract may be indeterminate, although it is of great aid in ruling out lesions of the esophagus, stomach, duodenum and colon as a source of trouble. Repeated attacks of cramping abdominal pain starting in childhood or even infancy, especially if associated with hemorrhage from the bowel, should put the examiner on his guard. Pain and tenderness in the region of the navel also is evidence. The surgeon who finds a comparatively normal-appearing appendix in cases in which the symptoms have pointed to appendicitis should explore the small intestine for a diseased Meckel's diverticulum. As with appendicitis, the troubles to which Meckel's diverticulum are heir are likely to be surgical emergencies.

We have been able to find records of only seven cases of malignant tumor in Meckel's diverticulum. The case presented here is the only one of fibrosarcoma that has been encoun-

MAYO CLINIC

Fig. 1. The tumor in situ. Origin from the tip of the Meckel's diverticulum and attachment to the fatty tissue over the dome of the urinary bladder are shown.

tered in the records of The Mayo Clinic. Hicks and Kadinsky operated on a boy aged twelve years for suspected appendicitis and found a perforated, infected carcinoid tumor of a Meckel's diverticulum, such as Lubarsch has described in the appendix, ileum and jejunum. Hässner operated on a man aged fifty years, and found a necrotic tumor which was thought to have originated from a Meckel's diverticulum; a diagnosis of acute appendicitis had been made. Crile and Portmann reported the case of a woman aged forty-one years on whom they operated for incomplete intestinal obstruction and encountered a fibrosarcoma of a Meckel's diverticulum. Tschiknawerow reported discovering at necropsy on a woman aged sixty-two years a spindle-cell sarcoma of a Meckel's diverticulum which had become necrotic and had perforated, causing generalized peritonitis. Kaufmann mentioned a spindle-cell sarcoma of a Meckel's diverticulum in the Basler Collection of Pathologic Specimens. Symmers described a malignant myoma springing from the base of a Meckel's diverticulum removed from a man aged twenty-two years; it was discovered by accident during the course of an operation for hernia. Symptoms traceable to its presence could not be elicited. Black's patient was a woman aged fifty-nine years, with a large myxomatous abdominal tumor. Its exact origin was doubtful, although it was believed that it arose from a diverticulum of the sigmoid which may or may not have been the remains of a vitelline duct.

REPORT OF A CASE

A man, aged sixty-two years, came to the clinic February 24, 1930, complaining of recurring hemorrhages from the rectum and a dull sensation of pressure in the left lower part of the abdomen. He had been in perfect health until fourteen months prior to admission, when he noticed tarry stools for two days. Weakness and pallor were noticeable at this time and he was anemic. Three months later he passed several ounces of bright red blood by rectum. Approximately every month since then he had had considerable bleeding from the rectum, at times bright red, at other times black and tarry. Appetite and digestion had been excellent. Aside from the indefinite sensation of pressure in the lower part of the abdomen, noticed only in the sitting posture, there had been no abdominal pain. A history of peptic ulcer could not be elicited. The patient had been moderately constipated for years. Slight edema of the lower extremities had been present following a febrile illness twenty years previously, probably phlebitis.

The patient appeared somewhat pale and the hemoglobin was somewhat below normal, 11.5 gm. for each 100 c.c. by the photo-electric method and approximately 65 per cent by the Dare method. The erythrocytes numbered 4,070,000 and the leukocytes 5,500 in each cubic millimeter. The systolic blood pressure was 155 and the diastolic 90. The pulse was 64 and temperature 98°F. Urinalysis, analysis of the gastric contents and roentgenograms of the thorax yielded negative results. Aside from diverticula of the descending colon, the roentgenograms with the barium enema failed to reveal evidences of a lesion. Abdominal mass was not palpable. Proctoscopic examination revealed hemorrhoids of moderate degree. The patient was told that the passage of the fresh blood could easily be accounted for by the hemorrhoids but that the old blood suggested a higher lesion. However, we felt that there was not enough evidence to warrant more than hemorrhoidectomy at this time, especially since stasis of blood in the rectum from bleeding internal hemorrhoids may occur, resulting in the passage of old blood.

Hemorrhoidectomy was performed March 3, 1930, and seven days later a severe rectal hemorrhage of old tarry blood occurred which the proctologists believed came from a point higher in the gastro-intestinal tract. The hemoglobin dropped from the previous level of 11.5 to 6.8 gm. for each 100 c.c. of blood. Pallor and weakness were marked. Several days after cessation of the hemorrhage the patient was reëxamined. Roentgenograms were again made of the esophagus, stomach, duodenum and small intestine, following the ingested barium meal, but a lesion was not demonstrable. Blood smears revealed a normal differential count and secondary anemia with moderately active regeneration. Special study of the blood did not reveal evidence of a hemorrhagic blood dyscrasia. Bleeding peptic ulcer, duodenitis, tumor of the small intestine, and ulceration of Meckel's diverticulum were considered.

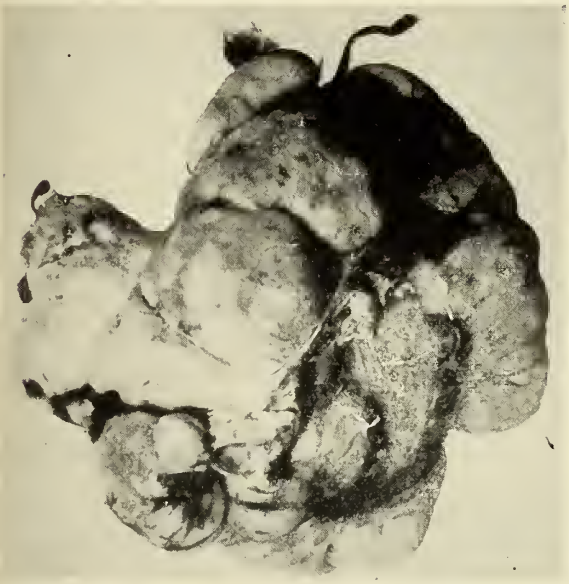

Fig. 2. The tumor and the Meckel's diverticulum after their removal. Gross ulceration was not demonstrated.

Exploration was advised. A transfusion of blood was given March 22, and March 25 exploratory laparotomy was performed (Fig. 1). A tumor approximately 7 cm. in diameter was found extending from the tip of a Meckel's diverticulum. It was superficially attached to the fatty tissue over the dome of the urinary bladder. The mass was dissected away from the bladder. The attachment was cauterized with the actual cautery and inverted with a double stitch of chromic catgut (Fig. 2). The diverticulum, together with the tumor, was dissected out with the cautery, without the application of clamps in order to keep well away from the growth. Neither gross nor lymphatic involvement was discovered. The opening in the ileum was closed transversely with three rows of chromic catgut and a single row of interrupted sutures of silk. There were no other abnormalities, aside from slight enlargement of the spleen. The Meckel's diverticulum was about 60 cm. from the ileocecal valve. Microscopic examination of the tumor disclosed fibrosarcoma 9 by 7 by 5 cm. (graded 2) in a Meckel's diverticulum (Fig. 3).

Convalescence was satisfactory. A communication from the patient, July 8, stated that he was in good health.

The clinical features of this case are entirely different from the malignant tumors of Meckel's diverticulum reported in the literature. Intestinal hemorrhage with secondary anemia was the only significant feature. Loss of weight, abdominal mass, and evidences of perforation, obstruction or inflammation were not present. Laboratory examinations failed to disclose the condition. This case illustrates the value of abdominal exploration in cases of indeterminate intestinal hemorrhage. Although the lesion is rare, it adds another to the list of causes of intestinal bleeding.

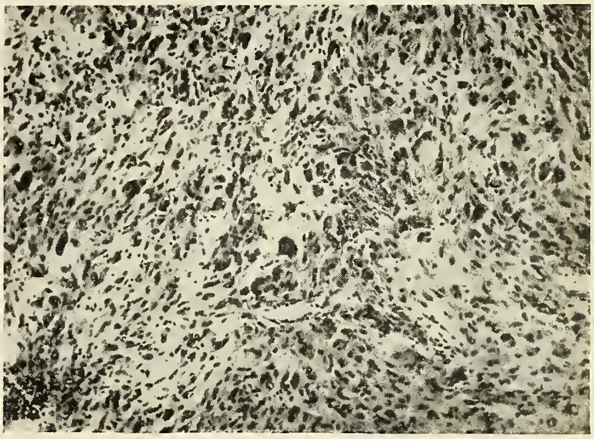

Fig. 3. Fibrosarcoma graded 2, with numerous thin walled blood vessels which undoubtedly were the sources of the repeated intestinal hemorrhages. Foci of lymphocytic cells are seen throughout the section.

FIRST AID BY THE MANUFACTURER.

Doctors received during the Christmas season a copy of the pamphlet entitled "First Aid and Emergencies," prepared by McKesson and Robbins for circulation to the public. It is not surprising to find from consultation of this pamphlet that first aid covers a wide variety of conditions and that apparently McKesson and Robbins have developed something for each of these conditions. Thus, anemia is listed among the conditions demanding first aid and the patient is given full instructions for its control. In addition, biliousness and liver trouble, Bright's disease, diabetes, eczema, gout, rheumatism and tuberculosis are among the conditions demanding first aid. True, the book mentions in various places the desirability of calling a physician, but the patient is encouraged to take a chance. This pamphlet represents one of the worst phases of proprietary medicine business. (Jour. A. M. A., January 3, 1931, p. 44.)

INSUROL IN DIABETES

"Insurol" is a nostrum sold on the mail-order plan by a concern or concerns known, variously, as the Official Products, Inc., and New Life Products Co. Insurol has been described as a "triumph of Germany's biochemical laboratories," and, it is said, "combines insulin with the actual substance of the pancreas gland." In diabetes quackery, two elements are nearly always found: The first is that of requiring the person who uses the nostrum to adopt a diet that is low in carbohydrates. The second, and more common, is that of incorporating in the nostrum a diuretic. The average diabetic patient has some rough-and-ready method of estimating the amount of sugar that is excreted. In a report regarding the assumed effects from Insurol, there are many factors that may explain the alleged reduction of sugar. (Jour. A. M. A., January 31, 1931, p. 378.)

IRRADIATION OF CARCINOMA OF THE CERVIX UTERI*

Harry H. Bowing, M.D., and Robert E. Fricke, M.D.
Rochester, Minnesota

THERAPEUTIC radiology has made substantial advances during its brief existence. The discovery of the roentgen ray dates back only thirty-five years and of radium only thirty-two years; their therapeutic application covers three decades. The discoveries were made abroad and hence the initial therapeutic applications were made there. Radium was first used in the treatment of uterine hemorrhage by Oudin and Verchère. Chéron was the first effectively to treat this same disease.

Among the earliest forms of carcinoma to be treated with radium was carcinoma of the cervix of the uterus. Carcinoma in this situation presented an urgent problem because of its prevalence and because surgical results had been far from satisfactory. It was well adapted to the new form of treatment because of the accessibility of the part to inspection and palpation, and because it afforded opportunity for microscopic examination of tissue. Radium was first used in carcinoma of the cervix in 1905, but not effectively used until Dominici, in 1907, introduced the principle of proper screening of applicators. Wickham, in Paris, working since 1906, published in 1913 the results of 1,000 cases in which radium was used. In early work, with small amounts of radium, not well filtered, the caustic effects predominated. After this pioneer work abroad, work was started in this country, and in 1915 Kelly and Burnam reported on their work with radium to the American Medical Association and the American Gynecological Society; this work dated from January, 1909. Irradiation for carcinoma of the cervix was commenced at The Mayo Clinic and at the Memorial Hospital in New York[13] in 1915.

Radium and roentgen treatment offer the only hope to sufferers from carcinoma of the cervix except for the achievements of surgery in early cases. In the few early cases diagnosed, both surgery and radium result as a rule in cure for at least five years. In most cases lesions are advanced and inoperable but radium and roentgen rays can salvage from 20 to 25 per cent for a period of five years, with a primary mortality of approximately 1 per cent. This result so far excels that achieved by surgery that less and less operating is done for this condition.

The results of irradiation are fairly constant throughout the world, although the diversity of methods of treatment is surprising. The main radiologic clinics of the world differ substantially in their methods of application, although the basic principles are fairly uniform. To illustrate this we will summarize the methods and results of a few of the radiologic clinics abroad and in this country.

In France, the pioneer, Regaud,[4, 22, 23] was the originator and is the chief proponent of the long-continued small dose. His technic is reproduced extensively abroad and in many places in this country.[19] Continuous irradiation is applied within the cavity of the uterus and against the cervix for a period of five to ten days. Forty to sixty milligrams are used, half intracervically and the remainder contracervically, three tubes in each position. Platinum screening of 1.0 mm. thickness is used with 2.0 mm. platinum screening on the vaginal tubes. The uterine applicator is a Para rubber catheter 6 cm. long, holding, usually, three capsules of radium. The intra-uterine capsules are filtered with 1 mm. platinum and 0.2 mm. aluminum foil. The capsule nearest the fundus contains 6.66 mg. radium element; each of the lower tubes contains 13.33 mg. radium element. The intra-uterine applicator hence usually contains 33.32 mg. of radium element, which in five days delivers 4,000 milligram-hours. The vaginal applicators consist of three or four capsules each containing 13.33 or 6.66 mg. of radium element; the strength of the wall is 1.5 mm. platinum and each is inserted in an ordinary cork, the walls of which are 0.5 cm. thick. The radium capsule is wrapped in aluminum foil and inserted in the center of the cork; the open ends are closed by plugs of cork and the applicator is immersed in boiling paraffin to sterilize it and to furnish an impervious coat. The corks to fit in the fornices are usually connected by a rubber-covered strip of steel, which also maintains the third cork against the face of the cervix. Usually 26.66 mg. is the total amount of radium placed in the vagina; five days of treatment will yield about 3,168 milligram-hours. Thus, using only about 60 mg. of radium, 7,200 milligram-hours is given in a treatment of five days.

---

*From the Section on Therapeutic Radiology, The Mayo Clinic, Rochester, Minnesota. Submitted for publication August 11, 1930.

The radium is removed daily, is cleansed, and is replaced after a vaginal douche has been given; treatment is stopped if the temperature rises above 101.5°F. or if the number of leukocytes in each cubic millimeter of blood falls below 3,500. Total dosage varies between 5,000 and 10,000 milligram-hours. External irradiation is used if the parametria are involved, and consists of highly filtered roentgen rays, as follows: 200 kilovolts, 4 to 5 milliamperes, 2 mm. zinc, 3 mm. aluminum, and 3 cm. wood filters, 60 to 80 cm. distance, six or more overlapping 15 by 15 cm. fields, one hour twice daily for a period of ten to twenty-five days; twenty-five to fifty-five hours of actual irradiation. This precedes the application of radium. Or, preferably, radium is also used for the external treatment: a lead cylinder containing 4 gm. of radium is placed over the eight pelvic portals at 10 cm. distance, for three hours daily. The total dosage amounts to 320 gram-hours (40 gram-hours for each portal). Locally there is considerable slough, which reaches its height the third week, when the toxic absorption is most marked. The rationale of the continuous small dose is to catch all carcinoma cells at the period of mitosis, ostensibly their most vulnerable phase. Following are the results at the Radium Institute of Paris:[4] thirty-eight early lesions, with 42 per cent of five-year cures; 132 borderline lesions with 28 per cent five-year cures; 149 inoperable lesions, with 10 per cent five-year cures, and thirty-one massive lesions with no five-year cures. Of the total 350 patients treated by radium and roentgen ray, seventy (20 per cent) obtained five-year cures.

In Stockholm,[4] the technic evolved by Forssell and Heyman,[14] and used since 1913, is founded on the following principles: (1) a small number of applications (three at most); (2) relatively large quantities of radium at each application, 100 to 120 mg. of radium element; (3) heavy filtration (filter equivalent to 3 mm. lead); (4) concentration of the whole treatment into a shorter period of time (three to four weeks), and (5) an interval of one week between the first two applications and of three weeks between the two last, with a total irradiation of about sixty hours.

The wall of the tube represents 1 mm. of lead and the wall of the applicator about 2 mm. For the secondary filtration, thin rubber is employed in the uterine cavity, and in the vagina two layers of thin paper and a thin layer of cotton-wool covered with thin rubber or oiled silk.

If the cervical canal can be dilated, radium is inserted into the uterine cavity at all three treatments, as well as against the vaginal surface of the tumor. The total dose in all three applications is 2,200 to 2,600 milligram-hours in the uterus and 4,500 milligram-hours in the vagina. In each of the three applications the uterus receives about 730 to 865 milligram-hours and the vagina, 1,500 milligram-hours. Each single dose entails about twenty hours of treatment. A typical series of treatments follows:

First treatment: In the uterus (4 tubes) 40 mg. × 19 hours = 760 milligram-hours. In the vagina (12 tubes) 78 mg. × 19 hours = 1,480 milligram-hours.

Second treatment: In the uterus (1 tube) 43 mg. × 21 hours = 900 milligram-hours. In the vagina (10 tubes) 71 mg. × 21 hours = 1,490 milligram-hours.

Third treatment: In the uterus (1 tube) 39 mg. × 19 hours = 720 milligram-hours. In the vagina (10 tubes) 80 mg. × 19 hours = 1,520 milligram-hours.

Aggregate dose: In the uterus 2,380 milligram-hours. In the vagina, 4,500 milligram-hours.

A specimen for microscopic examination is taken after insertion of the intra-uterine capsule.

Roentgen treatment in addition has been added since 1922 only for those cases in which isolated nodal metastasis or large parametric infiltration has been present at the commencement of treatment. Radium packs have also been used externally with encouraging results, but too recently to permit judgment of them.

The results have been as follows: 737 patients were treated from 1914 to 1923 inclusive; the condition of 25.5 per cent of these was operable. The primary mortality was 2.1 per cent. Among the 188 operable cases, 43.6 per cent of patients obtained five-year cures. Inoperable and borderline cases together, 549 in all, gave 16 per cent five-year cures, and 492 inoperable cases alone yielded 13 per cent five-year cures.

In Erlangen, Wintz is using roentgen treatment exclusively for carcinoma of the cervix. He uses two series of treatments, employing small fields, 6 by 8 cm. and 8 by 8 cm. In the first series, a full dose for carcinoma is given to the uterus alone. Eight weeks later treatment is directed to the parametria, and at the same time 80 per cent skin erythema dose is administered to the primary lesion. He reported 108 inoperable cases with 57.4 per cent five-year cures, and 632 inoperable cases with 12.3 per cent five-year cures. This method is a very severe one for the patient. Huge quantities of roentgen rays must be absorbed by overlying tissues from the rays directed to the lesion in the depths. It has not been possible to duplicate this work in this country, and cures have not been reported here to our knowledge from roentgen rays alone.

In Munich, the physicians of the Döderlein Clinic[7] are enthusiastic about the results of radium and roentgen treatment. Hysterectomy has been abandoned there since 1913. Von Seuffert reported 80 per cent of five-year cures in early cases in which the entire course of treatments was given. This record equals the report of 80 per cent of five-year cures by surgery alone given by Von Franqué.

Since 1918 roentgen treatment has been added to radium treatment. The method consists of two or more treatments at intervals of eight weeks.[4] In the first treatment sensitization of the tumor is attempted by application of roentgen rays to the pituitary body. Each temple is irradiated over an area 6 by 8 cm. as follows: at 200 kilovolts, 2.5 milliamperes, 30 cm. distance, and filtration is 1 mm. copper. Each field receives 30 per cent of the erythema dose. The following day roentgen rays are applied to the pelvis: 10 by 15 cm. fields are used, one abdominal and one dorsal exposure; 200 kilovolts, 2.5 milliamperes, 50 to 60 cm. distance and 1 mm. copper filtration; each field receives 90 per cent of the erythema dose. The pelvic irradiation is performed in one day if possible.

Biopsy is performed the following day, and the day after that radium is applied. Several tubes are placed within the uterus and cervix, aggregating 55 mg. radium element, filtered with 0.2 mm. silver, 1 mm. brass, and a layer of thin rubber. The radium is left in place for twenty-four hours. The vaginal applicators consist of several tubes with filtration of 1 mm. brass imbedded in corks; the total amount used is 55 mg. radium element and this is left in place twenty-four hours.

The second treatment, eight weeks later, is a repetition of that just recorded except that further irradiation of the pituitary body is omitted.

Results were gathered from 1,319 patients treated between 1913 and 1923 inclusive. The rate of operability in this group was 17.2 per cent. Considering the operable group, 163 patients received full treatment and 50.2 per cent obtained five-year cures. In twenty-five borderline cases in which complete treatment was given, 28.3 per cent of the patients obtained five-year cures; also 13.1 per cent of 543 patients with inoperable lesions and 1.2 per cent of 239 patients with massive lesions obtained five-year cures. The total rate of survival for five years among 1,216 patients who received the full treatment (103 stopped after one treatment) was 18.2 per cent.

In Switzerland, Fürst, at Zürich University, advocates roentgen treatment followed by radical hysterectomy (Wertheim's operation) six weeks later, and following this roentgen or radium treatment if malignant tissue cannot be entirely removed. If the growth has been cleanly extirpated, further irradiation is not employed unless recurrence occurs. The method is too recent to judge of its merit; results have not yet been published.

At the Radium Institute of Brussels, a utero-vaginal application is made first, involving dilatation for insertion of intra-uterine tubes and insertion of tubes in the fornices. Filtration consists of 2 mm. platinum and special rubber. One or two tubes are placed in the uterus and one in each lateral fornix; each tube contains 10 mg. radium element. The length of application is twelve to fifteen days, with removal and cleansing of the tubes every two days. The total dosage is 7,920 to 9,240 milligram-hours. In some cases, intra-abdominal treatment is added by performing laparotomy and placing needles and tubes containing 10 mg. at the base of each broad ligament. The radium is withdrawn after six days. Results are meager, as the Brussels Radium Institute is of recent development. In eleven operable cases, 54.5 per cent of patients obtained five-year cures; of fourteen inoperable cases, 35.7 per cent of patients lived five years.

In England, Cade is enthusiastic concerning his treatments with radium; the methods follow those of the Regaud and Belgian schools. Results are not yet published.

In this country, Kelly and Burnam were pioneers in this treatment.[17] They use the massive dose, given in one application, and see no advantage in small doses given for a longer time. Radon, in brass tubes with walls 2 mm. thick, is used. With the patient in the knee-chest position, two tubes are placed intracervically, and five to eight tubes (equalling in amount the intracervical radium) are placed in a gauze package against the face of the cervix. They consider this method to yield sufficient cross-firing without placing radium in the uterine canal. One thousand to 1,500 millicuries are used altogether. Two or more pieces of ¼-inch lead wrapped in gauze are placed above the cervix to protect the rectum, and the vagina is filled with gauze. Lead is not placed on the side of the bladder. The total treatment consists of 3,000 millicurie-hours, given usually in two hours' time. Extension in the parametria is taken care of by implantation of radon seeds through the vagina. Since 1924 high-voltage roentgen rays have been added to take care of parametrial extension, in cases which do not clear up in two months. In all cases, a piece of tissue about 2 by 3 mm. is taken for microscopic study. Patients are dismissed for three months following treatment. An extensive slough, with formation of a grayish-green membrane and foul discharge, occurs about a month after treatment. Two hundred thirteen patients treated prior to 1915 were traced. All patients, even if the condition was hopeless, were treated. Fifty per cent of the patients in the operable group were well after seven years, and of the inoperable group 7.8 per cent had survived for seven years.

In Philadelphia, at the University Hospital and the Philadelphia General Hospital, radium and surgery are used. Under general anesthesia trachelectomy is performed with the cautery whenever feasible, and the bladder is separated surgically nearly to the peritoneal attachment. Following excision of the cervix, 50 mg. of radium is applied to the canal and a like amount to the cervical stump, in a metal, T-shaped instrument devised by Clark; filtration consists of 1 mm. brass and 0.5 mm. aluminum. The duration of the treatment is twenty-four hours; the dosage totals 2,400 milligram-hours. Treatment is given in the dorsal position under anesthesia, with two retractors to expose the field. Biopsy is obtained at operation. A piece is removed from the edge of the cervix, not less than 2 cm. in diameter, and should include normal cervical tissue. There is diversity of opinion as to the advantage of roentgen treatment; it is given as a routine at the Philadelphia General Hospital and not at the University Hospital. Clark and Norris reported 28.5 per cent of five-year cures in early cases with radium alone, and 83 per cent of five-year cures in early cases with trachelectomy and radium, considering a total series of 214 cases. In the advanced cases, irradiation alone cured in 5.1 per cent for a period of five years, and irradiation and amputation by cautery gave a five-year cure in 20 per cent. All cases combined, irradiation alone cured in 5.9 per cent for five years, with a mortality of 1.4 per cent, and irradiation with amputation by cautery in 42.9 per cent with an operative mortality of 10.6 per cent.

In New York carcinoma of the cervix has been treated with radium at the Memorial Hospital[13] since 1915; treatment has been given in about 2,000 cases to date. Up to 1921, radium only was used, topically and also for external cross-firing. Since January, 1922, roentgen rays have been used for the external treatment, following the course of radium or in foul necrotic lesions preceding it. Healy stated that at least two-thirds of all his patients have parametrial involvement when first seen. Local recurrences are rare after five years, but recurrences in the parametrial lymph nodes may take place after six, seven, or eight years. Hence, particular attention is paid to cross-firing the parametria with external irradiation. High-voltage roentgen rays replaced moderate voltage in the last three or four years. The exposures are made at five portals encircling the pelvic girdle, the fifth one centered on the third lumbar vertebra to affect the prevertebral lymph nodes in this region. The factors given are as follows: 200 kilovolts, 0.50 mm. copper, 1 mm. aluminum, 50 cm. distance, 4 milliamperes, 60 to 80 minutes and 15 by 15 cm. Radium is applied intracervically in a two-tube tandem arrangement and in a vaginal bomb containing a large amount of the element. Six thousand millicurie-hours are given, half intracervically and half vaginally, within forty-eight hours. The combination of radium and intensive roentgen treatment produces from 400 to 6,000 per cent skin erythema dose throughout all parts of the pelvis. Interstitial application or needles are used only after several weeks if the lesion does not regress satisfactorily. This can be defined as the true massive dose. For the years 1922, 1923 and 1924 the following results are quoted: 44.5 per cent of five-year cures in the early and borderline cases. Recent results in inoperable cases are not given.

In New York at the Woman's Hospital Clinic, Ward employs radium by the method of inserting small amounts in the cervical canal, screened with brass and rubber, and placing needles 2 cm. apart throughout the cervix. The initial treatment is 2,400 to 4,200 milligram-hours. External irradiation is not used. Results in 134 cases were 53.1 per cent five-year cures in thirty-two favorable cases (operable and borderline lesions) and 23.1 per cent in all cases.

In Chicago, Schmitz[25] has been using radium and roentgen rays in this disease since the beginning of 1914. He uses radium in an intracervical applicator (two 25 mg. tubes in 1.5 mm. brass) for a period of twenty-four hours. High-voltage roentgen treatment is added, so that the irradiated region attains 110 to 130 per cent skin erythema dose. Schmitz[24] stated: "If we use radium without roentgen ray in cervical carcinoma we are at a disadvantage due to the rapid decrease of the intensity and therefore inhomogeneous distribution of the rays. The regional lymphatics cannot be effectively destroyed. If we employ roentgen ray without radium then we are limited by the tolerance of the skin to a low dose though a homogeneous distribution of the rays throughout the pelvis is attained. However, if we use a combination of radium and roentgen ray we can obtain a homogeneous distribution of a radiation intensity throughout the pelvis." Schmitz[26] reported his latest five-year results as follows: 78.27 per cent of five-year cures in early cases, 41.68 per cent in borderline cases, 12.42 per cent in inoperable cases, or a five-year salvage of 17.5 per cent in a total of 332 cases.

At Montclair, New Jersey, Stevens follows the Regaud technic, keeping his patients under influence of roentgen ray and radium for twelve weeks. The number of patients treated averages fifty a year, and 84 per cent of five-year cures are obtained in early cases, 42 per cent in borderline cases, 19 per cent in advanced cases, and no cures in cases of massive growths.

In Boston, Simmons and Leland employ radium at the Huntington Memorial Hospital. Formerly the treatment consisted of applications of screened radium, repeated every two or three months. At present, one heavy treatment only is given and that under general anesthesia. A patient receives about 5,000 millicurie-hours divided between silver-screened irradiation and gold seeds; the idea of using seeds is to prolong the exposure. The results, they state, have been very satisfactory but they are not yet published. Simmons and Leland are studying the results in 803 cases. In 1924 Leland reported three-year results with similar massive doses of so-called "unscreened" radium; the tubes of emanation were enclosed in steel jackets, and the glass seeds were left permanently. The radium was left in place for three to eight hours. A total dosage of 5,000 millicurie-hours was given. Of 165 patients, 147 were traced. The three-year results were as follows: 45 per cent cures in the favorable cases, 12.1 per cent in advanced cases and 12.7 per cent in the whole group. External irradiation was not applied.

In Buffalo, at the State Institute for the Study of Malignant Disease, Schreiner last year reported his method as follows: roentgen treatment is begun on the day of admission, by giving 25 per cent dose at a depth of 10 cm. The following day, the patient is placed in the lithotomy position, is put under general anesthesia, and the cervix is dilated and is filled to the internal os with tandem tubes containing emanation. These tubes are 5 cm. long and the filtration consists of 0.5 mm. gold, 0.5 mm. brass, and 1.0 mm. rubber. The tubes are left in position for a total of 1,200 millicurie-hours for each tube. Biopsy is performed before the tubes are placed. The day following removal of the radium, more high-voltage roentgen ray is given to bring the total irradiation (including the radium) to 130 to 140 per cent skin erythema dose. The whole treatment takes four to seven days. Five-year cures were secured in 64.28 per cent of early cases, in 28.57 per cent of borderline cases, in 14.47 per cent of advanced cases, in 1.44 per cent of cases of massive growth, and in 5.40 per cent of recurrent cases. The series consisted of 293 patients. The mortality was less than 1 per cent.

In Cleveland, Pomeroy gives a general anesthetic, obtains biopsy and dilates the cervix, then fills the canal from fundus to external os with tubes of radium element screened with 0.5 mm. silver, 1 mm. brass, and 1.5 mm. rubber, usually 75 mg. for thirty-six hours, or 2,700 milligram-hours. Glass or gold emanation seeds are implanted into the cervix in addition, usually twelve seeds of 1 millicurie each, with a dosage of about 1,584 millicurie-hours. The maximal dosage is 6,000 milligram-hours and millicurie-hours. Two hundred twenty-seven cases are reported; the proportion of five-year cures was 80 per cent in early cases (only five cases), 17.24 per cent for the entire group. The lesion was adenocarcinoma in more than half of the cases in which cure was effected. External irradiation was not used.

Technic and results at The Mayo Clinic will now be considered. There have been frequent changes in method since the inception of the treatment of the clinic in 1915. As it now stands intensive fractional dosage is employed; a massive dose is applied over a period of two to three weeks. The cases are first classified anatomically, according to the extent of the lesion.[1] Early or operable lesions are those limited to the cervical canal or to a small portion of the face of the cervix, and that they are early lesions is verified by biopsy. In borderline cases the lesion involves the face of the cervix and usually has extended to the parametria. Inoperable lesions are those extending to the vaginal walls or infiltrating the broad ligaments, usually with fixation. The recurring cases are those in which the carcinoma has reappeared after adequate surgical or radiologic treatment. Modified lesions are those treated elsewhere with some form of operation or irradiation, which evidently has proved inadequate, since the patients come with evidences of their former trouble.

The cases are also classified as to the type of treatment applied: whether complete, incomplete, limited, abandoned, or prophylactic. At the first examination we endeavor to place the patient in one of these groups, exercising our radiologic judgment. If the general condition seems satisfactory and a chance of cure appears possible, we endeavor to give a complete course of treatment, consisting usually of approximately eight applications of radium over a period of two to three weeks. The radium is given intracervically, interstitially, within the uterus, and vaginally, followed by one, two or three courses of roentgen treatment. The 50-mg. universal tube, filtered through 1.5 mm. monel metal, or a tube containing 50 millicuries of radon, enclosed in 0.5 mm. of silver and 1 mm. of brass, is the usual radium applicator employed. The duration of each treatment is twelve to fourteen hours. The entire length of the cervical canal and uterus is treated, applying usually two treatments to each 2.5 cm. of canal. In large cauliflower growths, radium in platinum needles is implanted, distributing the energy equally throughout the mass. The vaginal applications are made to the face of the cervix and in each fornix; the radium, besides its covering of monel metal, is shielded by 2 mm. of lead and 1 cm. of Para rubber. Treatments are given under direct inspection, with the patient in the knee-chest position; anesthesia is not required, except that with intra-uterine applications and with implantation, a Number 2 tablet of hyoscine, morphine and cactine is given hypodermically. After the applicator is placed, the vagina is packed with gauze. When radium is placed in necrotic craters, the applicator is enclosed in 2 mm. of lead to minimize further necrosis by filtering out the rays of longer wavelengths.

One complete course of radium only is given, unless local recurrences occur. For debilitated and cachectic patients with massive lesions a limited or palliative treatment is outlined. Following surgical removal of growths the treatment is given vaginally and is prophylactic. "Abandoned" cases are those in which our judgment has been at fault; that is, complications have developed if patients have no reserve strength to endure the treatments prescribed for them and treatment has had to be discontinued.

Our five-year results were recently reported, and include all cases treated with radium from 1915 to 1924 inclusive.[2] One thousand ninety-four patients were seen and of this number 1,001 (91.50 per cent) were traced. In this same period 167 patients were seen and not treated because of recent treatments elsewhere, or the hopeless extent of the condition. One hundred thirty-two patients were treated by surgical excision without irradiation, chiefly in the earlier of the years reviewed. Of the 1,001 patients treated and traced, 75 per cent of the small group seen early obtained a five-year cure, as did 61.53 per cent of those with borderline lesions, 21.49

per cent of those with inoperable lesions and 24.82 per cent of those with modified lesions. Of all four groups, there was survival for five years in 23.87 per cent, in 23.15 per cent with the modified group excluded, and in 66.66 per cent of the early and borderline lesions together. Of 625 cases in which biopsy was performed, 92 per cent were of epithelioma, 7 per cent of adenocarcinoma, and 1 per cent of mixtures of the two. Further analysis disclosed that 76 per cent of the lesions were graded 3 or 4, 15 per cent were graded 1 or 2, and 9 per cent were not graded. Analysis of five-year results by grade of lesion revealed that the small group with adenocarcinoma had the best survival; in grades 3 and 4 of both epithelioma and adenocarcinoma the best five-year survivals were obtained except in the modified group. Our mortality in hospital for the ten-year period was 1 per cent.

Comparison of radiologic results with surgical results is difficult, because the percentage of cases regarded as "operable" differs markedly with different surgeons. One surgeon will accept 15 per cent of all cases for operation; another will operate on 70 per cent of all patients that consult him. The radiologists also differ in classification, but on the whole radiologists are sought by patients in a far more advanced and hopeless condition.

Heyman,[15] in a report in June, 1927, before the Scandinavian Surgical Society, summarized the surgical statistics from twenty surgical clinics throughout the world (5,024 cases) and the radiologic statistics of seventeen radiologic clinics (3,512 cases). The five-year results in this massive collection were as follows: surgical cures for all cases, approximately 18 per cent; radiologic cures, 16.3 per cent; cures for operable and borderline cases by operation 35.6 per cent and by radiologic treatment 34.9 per cent; primary mortality for all cases, after operation 17.2 per cent, and after radiologic treatment approximately 2.0 per cent. Moreover of the total number of patients seen in surgical clinics, the condition was considered to be in an operable stage in 43 per cent, whereas of the total number of patients seen in radiologic clinics, the condition was considered to be in an operable stage in less than 30 per cent.

These figures approach each other closely, but the difference in the character of the initial material should be taken into account. The radiologic results are based on far more advanced and hopeless lesions, as shown by the condition, as regards operability of patients seen in surgical and in radiologic clinics.

SUMMARY

In this rapid review of methods and results in the largest radiologic clinics, we have found great variation in method with fairly uniform results. With radium, treatments may be given in two hours, and also in a month of constant irradiation, with all gradations between these extremes. The method at The Mayo Clinic lies between the massive dose and the fractional dose and embodies some of the advantages of each. In many parts of Germany roentgen treatment alone is used successfully; the results are not duplicated in this country. In four large clinics only (Baltimore, Stockholm, Cleveland, and Boston) radium is used without the help of roentgen rays.

In July, 1924, Greenough published the Report of the Committee on Treatment of Malignant Diseases with Radium and Roentgen Rays. Greenough's summary contained the information that in early and favorable cases of carcinoma of the cervix the choice between radium and operation is an open one. In advanced cases, the value of radium as a palliative measure is beyond dispute. In cases recurrent after hysterectomy, and in cases of carcinoma of the cervical stump, radium is the treatment of choice.

It must be remembered that either form of treatment, irradiation or operation, can effect cures only if the disease is local; if distant metastasis has occurred, surgery has nothing to offer, whereas irradiation may yield considerable palliation.

THE RELATIONSHIP OF EPILEPTIC SEIZURES TO BRAIN TUMOR*

Harry L. Parker, M.B. (Dublin)
Rochester, Minnesota

In the course of examination of patients seeking aid primarily because of epileptiform convulsions, there is the constant fear that sooner or later some of these patients may have signs of tumor of the brain. In the minds of both the lay public and the medical profession, a diagnosis of epilepsy seems to represent an unpardonable blunder if the patient later shows indications of gross cerebral disease. Further, in making a diagnosis of epilepsy it is usually assumed by both examiner and patient that not much can be expected in the future other than recurrent convulsive attacks. The question might be asked: How often does a convulsive seizure occur as the initial symptom in cases of cerebral tumor and is it possible for such seizures to continue over a long period before signs of tumor appear? Conversely, it is of interest to know the frequency with which cerebral tumors are found either before or after death in both institutionalized and non-institutionalized cases of epilepsy.

In a recent contribution on the subject[3] it was demonstrated that in a series of 313 patients suffering from cerebral tumor, sixty-seven (21.6 per cent) were found to have had generalized epileptiform convulsions some time during the course of the disease. It is noteworthy from the present standpoint that of these sixty-seven patients there were thirty-eight whose initial symptom was the convulsion. Fifteen patients, however, simultaneous with or even shortly after this initial convulsion, manifested unmistakable signs of tumor of the brain. It is obvious, therefore, that there might be no risk in making an erroneous diagnosis in cases in which signs of gross cerebral disease developed more or less rapidly shortly after the initial convulsion. Twenty-three patients had had a period of illness of varying length before the appearance of symptoms of tumor. During this period symptoms other than convulsions had not appeared. Ten of these patients suffered the usual course of symptoms of cerebral tumor within a year. Finally, a group of thirteen cases was isolated in which convulsive seizures had occurred for more than a year without any clue as to the real nature of the disease. This represents 4.1 per cent of the total series. In three cases seizures had occurred for many years before any other symptoms appeared. In the remaining ten cases the average time during which other manifestations than epileptiform attacks had not occurred was five and six-tenths years. It is probable that in all of these thirteen cases a diagnosis of epilepsy had been made years before the true nature of the trouble was suspected.

ABSTRACTS OF ILLUSTRATIVE CASES

Case 1.—A man, aged fifty-nine years, came to The Mayo Clinic February 16, 1922, because of convulsions and failing mentality. Twenty-six years before, he had begun to have convulsive attacks, usually at night when he was asleep. At first these attacks were three or four years apart; they gradually became more frequent until they had been about a week apart for the previous two years. Usually during attacks the patient bit his tongue and lost control of his urine. Six months before he came to the clinic the attacks changed in character and time of onset. Instead of generalized convulsions, he had short periods of loss of consciousness, usually lasting one to two minutes, during which he looked blank, stared straight ahead and acted in an automatic fashion and was usually confused for a half hour afterward. For a year he had noticed failing memory and difficulty in concentration. He had become increasingly irritable, and started quarrels at the least provocation. Several times during the previous year he had found himself in parts of the packing plant where he worked where he had no business and had wondered how he had got there. His wife stated that his mentality had become feeble and he had a tendency to talk at random and incoherently.

There was a fine tremor of both hands. All tendon reflexes were exaggerated. Speech was indistinct and there was a certain degree of paraphasia. Intelligence, coöperation and attention were considerably reduced. Roentgenograms of the skull showed a large osteoma in the frontal region involving the greater part of the left and the right frontal bones, but chiefly the left. There was no weakness of either side of the body and ophthalmoscopic examination of the eye grounds was negative. A diagnosis was made of osteoma of the frontal bone with underlying meningioma.

Craniotomy was done February 25, 1922. A huge meningioma was found 9 cm. in diameter arising from the left side of the falx cerebri, just above the left frontal sinus. It was extremely hard and filled with psammoma bodies. It had invaded the frontal bone. The patient recovered from the immediate effect of the operation and seemed to be getting along well when fever developed suddenly, with swelling and redness over the left eye and bridge of the nose. His neck became rigid. He was at first confused, then became comatose and died two days later, eleven days after the operation. Necropsy revealed the terminal cause as acute septic cerebrospinal meningitis.

---

*From the Section on Neurology, The Mayo Clinic, Rochester, Minnesota. Read before the Southern Minnesota Medical Association, Mankato, August 25, 1930.

Comment.—The interest in this case lies in the length of time before anything but epileptiform attacks became manifest. Grand mal became replaced by petit mal in the last six months of the patient's illness and it was only in the last year of the period ranging over a quarter of a century that other symptoms of a gross lesion of the brain became manifest. It might be argued that this was a case of so-called idiopathic epilepsy in which tumor of the brain had become superimposed. However, the type of tumor is that recognized as being extremely slow in growth, and, considering its relatively large size, twenty-six years was not too long for its life history. It had probably been present even longer.

Case 2.—A man, aged fifty-nine years, came to The Mayo Clinic May 16, 1926, because of convulsive attacks and increasing weakness of the left side of the body. Sixteen years previously, seizures had developed in which the left hand and arm would flex toward the mouth and be held then in tonic contraction. Relaxation would occur in less than a minute and the patient would appear normal again. These attacks might occur ten or twelve times a day, with a free period of from two to three weeks. There was no loss of consciousness. Eleven years before the tonic contractions took in the muscles of the head and face, the head and eyes would turn to the left and the face would contract. Six years before his admission to the clinic, the attacks changed in character and became more severe. Clonic jerkings appeared which progressed from the hand to involve the whole left side of the body or from the foot to the rest of the left side. Usually toward the end of the seizure consciousness was lost but was regained in from three to five minutes. One year before admission, progressive weakness, beginning in the left foot, had spread to affect the rest of the body. Memory had become poor, incontinence of bowels and bladder occurred, and the patient became confined to bed three or four weeks before he came to the clinic.

The patient was dull, apathetic and drowsy; he answered questions poorly and had an obvious memory defect. There was complete paralysis of the left side with ankle and wrist clonus, and Babinski's sign was present on plantar stimulation. There were apparently no sensory changes in the limbs affected. Roentgen examination of the skull was negative and changes could not be found in the eye grounds or visual fields. Spinal puncture showed clear fluid under pressure of 16 cm. of water with 1 small lymphocyte for each cubic millimeter of fluid. The Wassermann reaction of the blood and spinal fluid was negative. A diagnosis was made of subcortical tumor in the right cerebral hemisphere underlying the motor cortex.

June 2, craniotomy was performed with exploration of the brain. A purplish-red tumor with a definite outline was found to be approaching the surface of the brain in the right frontal and parietal regions. No attempt was made to remove it, but decompression was done. The patient died suddenly the second day after operation. Necropsy revealed a large glioma of the corpus callosum in the frontal region which had extended into the frontal, parietal and temporal lobes.

Comment.—The convulsions in this case were much more suggestive of gross cerebral disease. At the onset these were tonic and involved the left upper extremity. However, for ten years no other manifestations appeared and presumably general examination during this long time showed nothing abnormal. In the last six years the convulsions were more jacksonian in character. I have been led to believe that simple tonic contractions of one extremity lasting a relatively short time indicate a subcortical process. Later, as the tumor reached the surface, cortical irritation was characterized by jacksonian attacks. Finally, in the last year paralytic symptoms appeared and diagnosis was no longer difficult. The tumor was also different, being gliomatous in character but again of excessively slow growth.

Case 3.—A woman, aged thirty-eight years, came to The Mayo Clinic February 2, 1927, because of convulsions and headaches. For ten years she had lost consciousness once or twice a year: the longest interval between the attacks had been two years. The attacks were preceded by an aura of inability to talk which lasted about a minute, was followed by a turning of the head to one shoulder, loss of consciousness and falling. During the attacks she was cyanosed and had clonic jerking of all extremities. Occasionally she did not sleep, and then slept soundly for several hours. There had also been a few minor attacks consisting of transitory loss of speech. A year before she came to the clinic occipital headaches appeared; these increased in frequency and severity and became associated with vomiting. Two weeks before examination she had noticed slight blurring in vision in reading and writing and occasionally transient diplopia.

The patient was well developed and well nourished, not apparently acutely ill, and there were no signs of mental impairment. Ophthalmoscopic examination showed acute papilledema of about 4 diopters in both optic disks. Roentgenograms of the skull showed slight enlargement of the sella turcica with thinning of the posterior clinoid processes. Tendon reflexes were increased on the left side of the body; there was slight loss of speed on that side, and although the gait showed nothing unusual the patient could not hop as well on the left limb as on the right. A diagnosis was made of tumor of the cerebrum in the right frontotemporal region.

Craniotomy was performed February 15, 1927. A large subcortical tumor was found. No attempt was made to remove it, but decompression was done. The patient died three days later. Necropsy showed a large, subcortical glioma of the brain in the left frontoparietal region.

Comment.—In nine years this patient had had seizures that resembled epilepsy; then the headaches and visual disturbance gave a clue as to the nature of the disease. The aphasic type of aura might have led to a suspicion of tumor, since this is not common in cases of epilepsy, but at the outset the diagnosis was difficult and the period of waiting for further developments was necessarily a long one. Ventriculography or encephalography would have helped in this case had the true condition been suspected early.

Case 4.—A man, aged forty-one years, came to The Mayo Clinic August 2, 1923, because of convulsive attacks. He stated that he had had these for nine years and although at first they came two or three times a month they had gradually increased to the same number in a day. They occurred both during the day and at night. Usually he had a warning in the form of a peculiar sensation in the forehead and eyes, lasting a half minute to two minutes. Sometimes he sat or stood while unconscious, but frequently he fell, bit his tongue, and urinated and defecated involuntarily. A few weeks before examination he had had eight attacks in twenty-four hours. Occasionally frontal and orbital headaches occurred after the attacks, but otherwise headaches were not persistent or severe. His greatest concern was his inability to hold a position as printer, for his employers were afraid of his being injured by machinery during these attacks. Except for these seizures he felt perfectly well and had had no mental disability.

The patient came to the clinic alone and there was no opportunity to get a description of his seizures. At the first examination he seemed physically well and was advised to return for completion of examination the next day. After an absence of three days he was admitted as an emergency case to the hospital in a stuporous condition. According to his landlady, he had apparently been well the first day, although depressed. The second day he complained of severe headache and remained in bed most of the day. The third day he was worse, did not take food and complained bitterly of headache and nausea. The day of his admission to the hospital he had become drowsy and stuporous, vomited and had a convulsion.

In the hospital the patient did not talk and responded poorly to stimulation. Ophthalmoscopic examination showed the right optic disk to be slightly elevated on the nasal side but the left optic disk was normal. The pupils did not respond to light, all tendon reflexes were active and equal, there was no muscular weakness, and Babinski's sign was absent. The stupor increased throughout the day and the patient died in the evening without regaining consciousness. Necropsy showed a hemorrhagic, cystic glioma of the left temporal and frontal lobes. There had been a terminal hemorrhage into the tumor.

Comment.—This type of death is by no means uncommon in cases of tumor of the brain. The rapid and sudden change in the patient's condition is extremely disconcerting when a diagnosis of epilepsy has been made and a grave prognosis has not been offered. However, in spite of this case and Cases 1, 2 and 3, it must be insisted that in most cases such a sequence of events is fortunately not the rule. The more usual situation is illustrated in Case 5.

Case 5.—A woman, aged fifty-six years, first came to The Mayo Clinic June 7, 1922, complaining of convulsive attacks, epileptiform in character. She had had her first convulsion two years before. The attacks occurred every three months, were moderately severe, but symptoms were absent between attacks, except for slight failure in memory. She did not remain at the clinic to complete her examination. A diagnosis was not made. The patient was seen again January 25, 1925. This time, however, she was brought to the clinic in an ambulance and was in deep stupor. In the interval the attacks had become more frequent and more severe and were preceded by transitory unpleasant tastes and odors. A year before this admission the attacks had ceased suddenly and had remained absent for eight months, but mentally the patient became dull, forgetful and apathetic. Two months before the second visit all symptoms returned and were more severe. Headaches, nausea and vomiting came between the convulsions, and, following a more severe convulsion a few days before admission, complete left hemiplegia had developed with progressive stupor and involuntary urination.

Examination was limited because of the stupor, but complete flaccid paralysis of the left side of the body was noted. Eye grounds were normal and the spinal fluid was not under great pressure. Because of the history of convulsions with olfactory and gustatory aura, the left hemiplegia and progressive downward course, a diagnosis was made of tumor in the right temporal lobe. The patient died four weeks later and necropsy proved this diagnosis to be correct.

Comment.—In this case the period of convulsions as a solitary symptom of tumor of the brain was only three years. The whole course of the disease, as judged by symptoms, was four and a half years. Presumably a correct diagnosis could have been established during the last eighteen months, and possibly earlier, for the increase in frequency and severity of convulsions and the appearance of uncinate symptoms would have indicated a progressive gross cerebral disease, and very soon other signs appeared which would have confirmed the suspicion.

GENERAL COMMENT

The relatively long period these patients had convulsions before any other symptoms appeared and the exact relationship of the tumor to the convulsive seizures are problems of interest. In a previous study[3] emphasis was placed on the relatively small number of cases in which convulsive seizures occurred during the course of intracranial tumor. This is actually only 21.6 per cent of the 313 cases, and for every case in which convulsions were associated with the tumor of a certain character in a certain situation, one or more other cases could be demonstrated of an identical nature, but convulsions had never been a prominent symptom. It may be assumed, therefore, that although convulsive seizures are relatively more common in cases of intracranial tumor than in the general run of disorders, some other factor than the tumor itself must be held responsible for the appearance of the convulsions. Four and one-tenth per cent represents the greatest number of cases of tumor that might have been mistaken in the beginning for cases of epilepsy.

From the standpoint as to the relative incidence of tumor in cases that have been diagnosed as epilepsy, some interesting figures are now available. In necropsy cases at Craig Colony cerebral tumor was found to be present in 2 per cent, and in a group of necropsy cases in Australia the incidence was 3.5 per cent. Lennox and Cobb, in a recent article drawn from the study of a large number of non-institutionalized, adult epileptic patients, have found the incidence of tumor to be 3.5 per cent. Therefore, if an adult patient has had convulsions for a relatively short time without manifest signs or symptoms of disease other than convulsions, the possibility of the presence of tumor cannot be estimated as more than from 3 to 4 per cent. Obviously the shorter the history and the fewer the convulsions the more guarded should be both diagnosis and prognosis. It is better to confess ignorance and doubt than to proceed to label the condition with a hard and fast diagnosis that is to last for all time. If tumor is suspected, the diagnosis may be confirmed early and well in advance of clinical signs and symptoms by ventriculography and encephalography. This, however, cannot be recommended as a routine procedure in all cases of convulsive seizures and these tests carry their own fallacies and possibilities of misinterpretation. A more conservative plan of waiting and frequent, careful examinations with an open diagnosis is wiser in cases of adult patients in which convulsive seizures have developed recently. At no time should the possibility of tumor be forgotten and an effort should be made to exclude its presence by careful examination. At the same time it is of some comfort to know that the margin of error is no more than between 3 and 4 per cent and there is plenty of time in which to make a correct diagnosis. In the majority of cases of cerebral tumor a diagnosis is possible early, and correspondingly in most cases in which epilepsy has been diagnosed the possibility of tumor is not great.

BACKACHE FROM THE ORTHOPEDIC VIEWPOINT*

Ralph K. Ghormley, M.D.
Rochester, Minnesota

WHETHER or not modern methods of living have actually increased the incidence of the complaint "backache" cannot be determined. It may be surmised that riding in automobiles has caused at least a small increase in the number of such cases. In order to furnish a basis for considering this complaint, I have reviewed 100 consecutive cases of pain in the back; it was not the chief complaint in all cases, but in most it was one of the major complaints.

Forty per cent of the patients were men and sixty per cent were women; about 75 per cent were between the ages of thirty and fifty years and none was aged less than twenty years. Although statistics would vary in a larger series of cases, they nevertheless furnish a fair basis for comparison (tabulation).

TABULATION

CAUSES OF PAIN IN 100 CASES OF BACKACHE

		Cases
Sacro-iliac affections		32
Lumbosacral affections		23
Lumbosacral strain	9	
Anomalies of the fifth lumbar vertebra	4	
Narrow fifth lumbar disk	4	
Calcified iliolumbar ligaments	4	
Spondylolisthesis	2	
Arthritis (including spondylitis deformans)		24
Postural strain		5
Old fractures		4
Old Pott's disease		3
Scoliosis		2
Adolescent round back		2
Paget's disease		1
Congenital anomaly of the first, second and third lumbar vertebræ		1
Metastatic malignant disease		1
Congenital anomaly of sacrum		1
Tumor of the cauda equina		1

SACRO-ILIAC AFFECTIONS

The predominance of sacro-iliac affections is not as great as would seem to be indicated, because several cases have been included in which the lumbosacral as well as the sacro-iliac joints appeared to be affected. Cases are included of arthritis and of strain, unilateral and bilateral. Accurate distinction between strain and arthritis in these joints is often difficult, unless the arthritis is a part of generalized arthritis of the spine. More often the arthritis is traumatic, due to the long-continued strain to which these joints are subjected, and in most cases of so-called strain originate in early arthritis of traumatic origin. The symptoms of this condition are not always clearly defined.

The most significant physical signs are pain localized over one or both sacro-iliac joints with or without sciatic radiation, tenderness on pressure over the posterior sacro-iliac ligaments, and over the region supplied by the superior gluteal nerves, pain on internal rotation of the femur on the side affected due to the pull on the external rotators of the hip joint which attach across the sacro-iliac joint, and limitation of straight leg raising; the last is usually dependent on the presence or absence of sciatic pain with its accompanying spasm of the hamstring muscles. In the more acute cases there is usually a good deal of spasm of the erector spinæ muscles and there may be a lateral list of the spine, usually away from the side affected (sciatic scoliosis). An almost constant observation in such cases is pain on pressure over the anterior sacro-iliac ligaments on rectal examination. The roentgenogram is not particularly helpful in making a diagnosis. In good stereoscopic pictures changes can be detected in many cases, but a single flat roentgenogram is often misleading and too much stress should not be placed on its interpretation.

LUMBOSACRAL AFFECTIONS

In many cases signs pointing to involvement of the lumbosacral joint accompany signs of sacro-iliac affection. Usually there is tenderness over the fifth lumbar spinous process on heavy percussion and there may or may not be tenderness laterally over the transverse processes. These lie deeply imbedded beneath the muscles, and pressure there, except if subjects are thin, is often not the cause of pain. Many believe, however, that the distinction between sacro-iliac and lumbosacral lesions cannot be clearly drawn in some cases. This no doubt is true because of the complex ligamentous structure holding these joints together. It is easy to see how strain or arthritis involving one joint may throw an added burden on the other joints and thus produce symptoms referable not only to the original joint, but to both of the others.

---

*From the Section on Orthopedic Surgery, The Mayo Clinic, Rochester, Minnesota. Read before the Southern Minnesota Medical Association, Mankato, August 25, 1930.

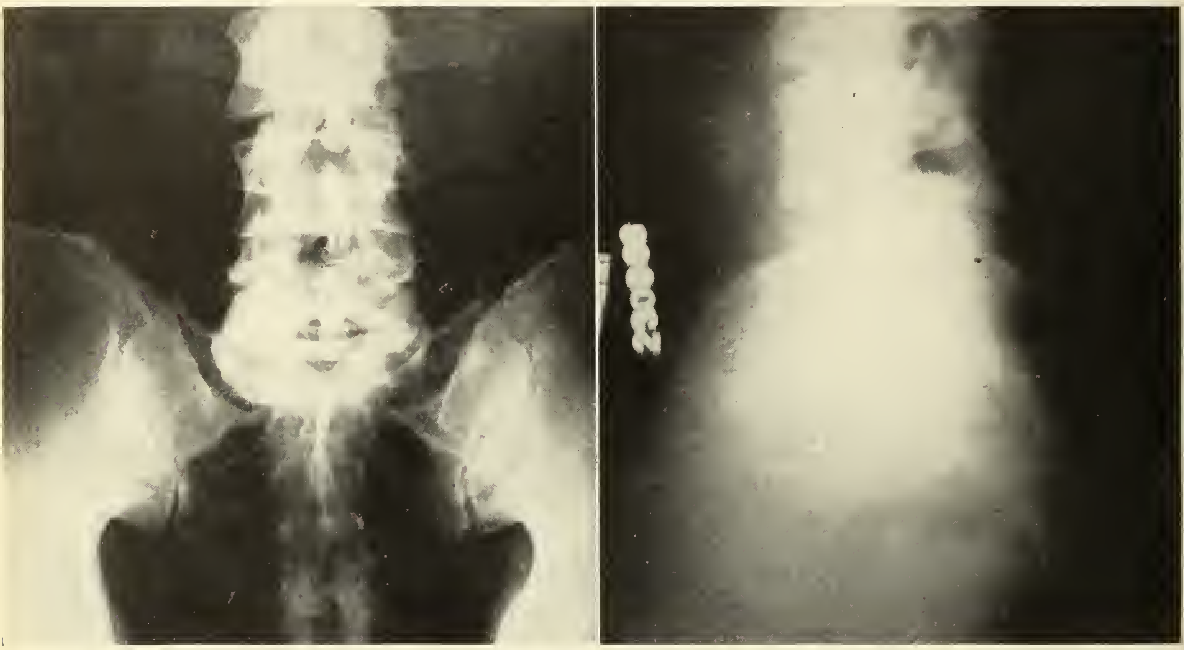

Fig. 1. The roentgenograms show narrowing of the intervertebral disk between the fifth lumbar vertebra and the sacrum, and also some change between the fourth and fifth lumbar vertebræ.

Congenital anomalies of the lumbosacral area are: sacralization, either unilateral or bilateral, spina bifida, anomalies of the articular facets between the fifth lumbar vertebra and the sacrum (Goldthwait), and anomalies in the laminæ. All of these have been considered as etiologic factors. I believe that spina bifida, except in the presence of actual change in the nerves, is rarely, if ever, the cause of backache. Sacralization may be the cause, but sacralization produces a firmer type of joint, and careful examination of a good lateral roentgenogram usually shows the fifth lumbar vertebra fused to the sacrum. This would exclude any possible motion except between this joint and the vertebra above.[2] Anomalies of the laminæ causing weakening, which some observers believe to be the cause of spondylolisthesis, can only be demonstrated in the best stereoscopic roentgenograms. Keith stated that there is no evidence to suppose that the separation of the arch of the last lumbar vertebra is the result of maldevelopment. Keith also considered the evolution of the human spine, pointing out that from the quadruped posture to the erect posture many important changes have taken place, among which are the shortening of the lumbar trunk and the widening of the pelvic base. This process of evolution is perhaps not complete. It is because of this that so many anomalies are found in this region. The trunks of our predecessors were longer and not so heavily built. The sacrum was placed more on a plane with the rest of the spinal column. In the change from the horizontal to the erect posture a much greater strain has been thrown both on the lumbosacral and on the sacro-iliac joints. Lumbar lordosis has developed; in some cases it is exaggerated so that the angle between the sacrum and the lumbar portion of the spinal column is almost a right angle. This no doubt places an undue strain on the ligaments supporting this area and tends to produce strain. These evolutionary changes, therefore, must be recorded as definite predisposing factors in many of these cases of low backache.

Another condition met with frequently enough to warrant special consideration is partial destruction of the intervertebral disk between the fifth lumbar vertebra and the sacrum (Figs. 1 and 2). This condition was noted in four cases of the series. Trauma is usually the cause; a severe injury may cause partial rupture of the disk which is not recognized at the time, but which gradually leads to diminution in the thickness of the disk with probable fibrosis of the cartilage. Often in such cases there is a history of recurrent attacks of pain, rather severe at the time and clearing up in two or three days. Except for tenderness over the lumbosacral area and more or less spasm of the lumbar muscles, the results of general examination are negative and a lateral roentgenogram centered over this area must be relied on to make the diagnosis. The pathologic change in these cases must be similar in many respects to that seen in spondylolisthesis; hence the treatment should be similar. In many of the cases a brace or high-backed belt or corset will suffice, although a fusion type of operation is indicated.[1]

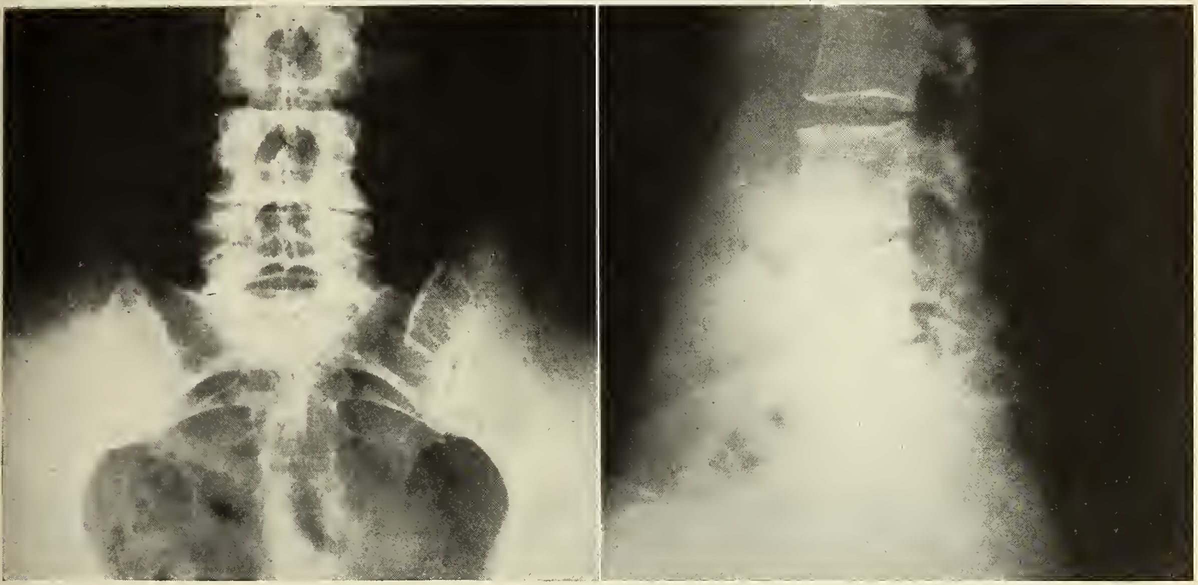

Fig. 2. Narrowed disk between the fifth lumbar vertebra and the sacrum with some calcification along the margin of the disk, best shown in the anteroposterior view.

In the anteroposterior view of the lumbosacral portion of the spinal column one may occasionally see a definitely calcified band running from the transverse processes of the fifth lumbar vertebra to the iliac crests. The iliolumbar ligaments are heavy structures whose attachments are such that they support the fourth and fifth lumbar vertebræ, as well as the upper portion of the sacrum, acting as slings with their attachments to the anterior surface of the ilium. The exact significance of this calcification is not clear, but the fact that it is usually seen associated with pain low in the back, particularly referred to the iliolumbar angle, is of considerable importance in their interpretation.

Spondylolisthesis was found in two cases of the series. In one of the cases it appeared to be superimposed on a congenital anomaly. In the other case traumatism was the cause. The diagnosis in the more severe types of the condition is usually not difficult, even without roentgenologic examination. In all cases it should be discovered in a good lateral roentgenogram centered over the lumbosacral joint. The treatment should be operative with an autogenous bone transplant. A brace may relieve the pain, but usually it has to be worn indefinitely.

ARTHRITIS OF THE SPINE (INCLUDING SPONDYLITIS DEFORMANS)

Arthritis was diagnosed in twenty-four cases. The term arthritis refers to at least three types:

The first type is so-called hypertrophic arthritis or osteo-arthritis, in which the roentgenogram shows hypertrophic spurs about the margins of the vertebral bodies and around the articular facets. These hypertrophic changes are significant. They may often occur without symptoms. However, when a more or less severe strain is superimposed on such a spine symptoms are produced and treatment must be commenced. Usually the pain occurs after periods of rest, and wears off after periods of activity.

In the second type are cases in which the roentgenograms show, besides a moderate amount of spur formation, a definite atrophic condition of the vertebral bodies, which is not clearly understood. It is not entirely due to disuse. It usually occurs in older persons and may in the more advanced cases be accompanied by a pathologic fracture. It is not typical osteomalacia, although it has some resemblance to this condition.

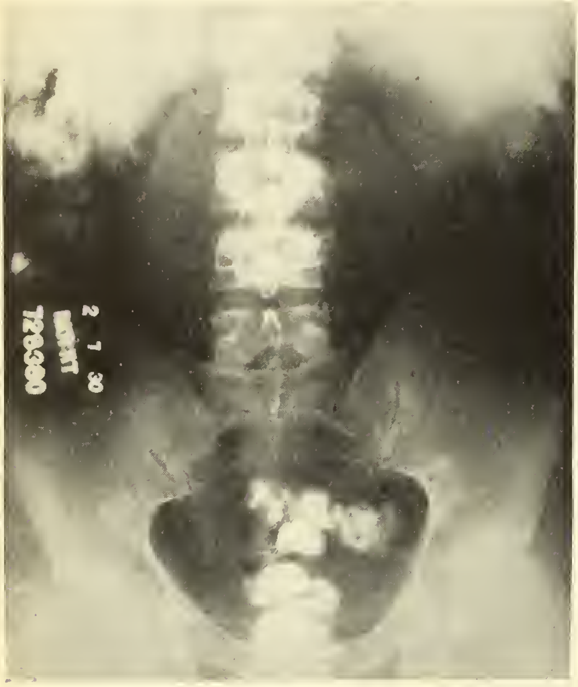

Fig. 3. Arthritis of the lumbar spine, gonorrheal in origin. Changes in the articular facets of the third and fourth lumbar vertebræ on the left may be noted.

The third type is again quite different in that its change is primarily in the ligaments, which by almost complete calcification finally fuse the spine into one solid rod. I refer to what is usually spoken of as spondylitis deformans of the Marie-Strümpell type. Little is known about the etiology of this condition, although it is classified as arthritis. The process is usually confined to the spinal column and sacro-iliac joints. The change is apparently primarily in the ligamentous structures, which become calcified. Subsequently the intervertebral disks and articular facets become involved. The end-result is the "poker spine." The main complaint is stiffness. Pain is usually not severe although it may be quite troublesome. One case is of special interest because of its unusual character.

A man, aged thirty years, following acute urethritis seventeen months previous to his admission to The Mayo Clinic, had had active acute arthritis of the right knee. At about the same time he had had severe pain in the lumbar region which lasted about two weeks and then subsided. Since that time he had had occasional attacks of rather severe pain in the lumbar region for two or three days. Examination disclosed rather marked limitation of motion of the lumbar portion of the spine, but without much tenderness or pain. The roentgenogram (Fig. 3) revealed a rather unusual picture. In the stereoscope one could see actual destruction of one articular facet and partial destruction of another. Also there was considerable periosteal proliferation about that area. Because of the coincidence with what seemed to be typical gonorrheal arthritis of the knee it was felt that this was of the same origin involving the articular facets of two lumbar vertebræ.

POSTURAL STRAIN

Five cases are classified in this group. In the main there are two types of backache due to faulty posture: that experienced by the large heavy person with a heavy abdomen, causing a constant drag on the ligaments and producing symptoms, and that experienced by the thin person with poor musculature who stands with round shoulders and marked lordosis. In many of the other conditions also, posture plays a certain part in the production of symptoms, since many of these patients are relieved when the strain of standing is removed. One may easily be too much inclined to regard faulty posture as the cause of many backaches, but it does no doubt exist as a factor and postural exercises carefully supervised will be of help in many cases.

OLD FRACTURES

In four cases of the series old compression fractures of the vertebræ were present. Two were in the midthoracic region and two in the thoracicolumbar region. In only two cases was the pain severe, and in these the condition had not been recognized previously. Owing to radiation of pain the complaints had been of abdominal distress. In such cases a lateral roentgenogram of the thoracicolumbar portion of the spine may clear up the diagnosis at once. It may be wise to operate in a few cases, although in many cases a brace and baking and massage over a period of a few weeks afford relief.

OLD POTT'S DISEASE

Old Pott's disease was discovered in three cases. In one case the symptoms were mild, the condition having apparently healed spontaneously.

In the other two cases symptoms had existed for a year or more. The pain in tuberculous spondylitis is rarely severe and may often be endured for months before the patient consults a physician, usually on account of deformity. The stage of deformity, however, is too late in which to get the best results from treatment, which should be operative on adult patients unless contra-indicated by other complicating conditions.

MISCELLANEOUS CONDITIONS

Scoliosis with nerve root pain, adolescent round back, Paget's disease, wedged vertebræ due to congenital anomaly, metastatic malignant disease, congenital anomaly of the sacrum with secondary changes in the cauda equina, and tumor of the cauda equina were among other conditions discovered. These conditions are not common, it is true, but they may be considered as possibilities. Malignant disease should always be suspected when intractable pain is present. It is the most persistent and the most severe type of pain in lesions of the spinal column. It usually does not respond to rest or fixation of any type and often can only be controlled by heavy doses of opiates or by cordotomy.

Tumor of the cauda equina should be a reminder that the central nervous system should be considered in all cases of backache. Neurologic consultations were called for in twenty-six cases of the series. Positive data other than sciatica were found in two cases only. Neurologic examination made as a routine in all cases would be desirable, but as one becomes more familiar with such cases it is possible to select the suspected neurologic cases. In many cases of sciatica such examinations are done. If the pain is not typically sciatic or if it is felt that the diagnosis is not adequate, the neurologist should be consulted.

TREATMENT

In general the same principles of treatment apply to the spinal column as to other joints, such as rest either by fixation by some form of splint or support, or in bed, and traction, heat and massage properly applied. No particular type of support is recommended. Women may wear a good, properly fitted corset. The use of extra pads and straps is not necessary, but it is important to have an exact fit. In cases of sacro-iliac affections a belt around the pelvis helps greatly. In cases of lumbosacral affections it is necessary to run the support up along the lumbar portion of the spine to the thoracicolumbar region. The use of physiotherapy is usually indicated. Baking, massage and graduated exercises are the most helpful procedures in this line.

What is more important perhaps than the type of support used, is the reassurance given the patient that his condition is not serious, and that he can be cured. His activities must be regulated and his coöperation must be secured. Too many such patients go from one physician to another and to osteopaths and chiropractors, and thus their troubles are prolonged. They must be made to realize this, and when they do realize it they will be better satisfied and will respond to treatment more quickly.

There is a decided tendency toward operative treatment of the lumbosacral and sacro-iliac disorders. The wide variety of opinions among orthopedic surgeons regarding such operation can mean only that the surgeons are dissatisfied with the operative results. Excellent results may be obtained from operative treatment, but cases must be carefully selected and accurate diagnosis must be made. Even then the question arises: will the patient get well on the long postoperative regimen which is essential if operation is not performed?

THE IMPORTANCE OF TOXIC GOITER COMPLICATING OR COMPLICATED BY OTHER CONDITIONS REQUIRING SURGICAL INTERFERENCE*

CHARLES MAYO, 2nd, M.D.
Fellow in Surgery, The Mayo Foundation
Rochester, Minnesota

A PRECEPT handed down from surgeon to surgeon is that if one of two coexistent operative conditions is toxic goiter (exophthalmic goiter or adenomatous goiter with hyperthyroidism), the goiter should always be given attention first. It seemed wise to consider the reasons for the initiation of such a precept and to try to determine the truth or falsity of it.

The relative importance of this matter can be realized by considering the frequency with which two such conditions do exist in the same person. At The Mayo Clinic, in 1927, 2.37 per cent of the patients with exophthalmic goiter and 7.3 per cent of those with toxic adenoma had complicating conditions which required operation.

There is no question but that, today, the picture of toxic goiter, in most sections of the country, is entirely different from that which was prevalent only a few years ago. The milder form has been brought about by education, prophylaxis with iodine, and surgical treatment at an early stage of the disease. Uncomplicated, the risk in those cases seen in former years brought premature gray hair to many a doctor's head. These patients needed little in the way of surgical shock to throw them into a state of postoperative toxemia, which resulted too frequently in death.

The clinical picture in such a case is represented by a sudden rapid rise in temperature and pulse, out of proportion to that which would be expected from the surgical procedure involved. Both remain relatively high. The pulse, as time goes on, due to added strain on the heart, becomes irregular. Maybe fibrillation enters the picture, and in quality the pulse becomes weak and thready. The patient sweats freely; respiration gradually becomes rapid and shallow; vomiting and delirium may develop, and, as the progress is uninterrupted, diarrhea, coma and death follow.

When two diseases coexist, one of which is concerned with the thyroid gland, and when care in the development of a complete history of the case is not taken, often the condition of the thyroid gland may be overlooked, due to the fact that the patient's only complaint obviously points to the other disease. It is not amiss therefore to repeat an axiom that at all times one must be looking out for masked symptoms.

This may be more clearly illustrated by citing the case of a patient who entered the clinic with a draining sinus in the region of the gallbladder, following cholecystotomy performed elsewhere seven months previously. Attention obviously centered about the causes of such a condition. A complicating exophthalmic goiter was not recognized until just prior to a planned exploration. Possible trouble was thus fortunately averted. An interesting fact which developed during convalescence from the primary operation for the goiter was the appearance of a sponge at the outlet of the draining sinus. This was removed. A few days later, cholecystotomy was done, at which time two stones were removed. One was the size of a walnut; the other a smaller stone, the size of a filbert, was impacted in the cystic duct. Following this the patient made an uneventful recovery.

Occasionally, after operation, a condition simulating a mild thyroid crisis develops, but preoperatively the complicating disease was unrecognized. Such a postoperative complication is mainly cardiac in nature, and it reacts favorably over a period of a few days to administration of compound solution of iodine (Lugol's solution). The possibility of such a cause for such a sequence of events must necessarily be kept in mind.

The following case may be taken as an example:

A married woman, aged forty-six years, came to the clinic August 17, 1926, complaining of "falling of the womb," which had gradually increased in severity in the last twenty-three years. She was the mother of eight children who were living and well, but her condition had become definitely worse following the birth of her last baby two years previously. The uterus and vaginal walls were so greatly prolapsed that they would have to be manually replaced after the patient walked across the floor. No other important features were brought out in the history.

---

*Read before the Southern Minnesota Medical Association, Mankato, Minnesota, August 25, 1930.

General examination centered around the pelvis, and the diagnosis was of relaxation of the anterior and posterior vaginal walls, and cystocele, rectocele, and prolapse of the cervix and uterus, all graded 3. The fundus and fornices were normal. The blood pressure at the time of examination was 115 systolic and 70 diastolic. The pulse rate was 80 beats a minute. The tonsils were infected, graded 3.

August 24, the patient was operated on for the pelvic condition. The procedure was uneventful but postoperative progress was stormy. On the day after operation, the temperature exceeded 105° F. and the pulse rate varied between 125 and 160.

A medical consultant reported that the thyroid gland was enlarged, firm and slightly irregular but that no adenomas were found. A bruit, graded 1, was heard at each upper pole. Fine tremor, graded 2, was present. The systolic blood pressure was 132 and the diastolic 78. The consultant thought the patient's condition was probably due to a hyperthyroid reaction. He recommended that compound solution of iodine be given daily in doses of 50 drops, either by mouth or by proctoclysis.

The pulse and the temperature remained elevated. August 27, the cardiac rate was rapid and extrasystoles were present. Bronchopneumonia of the base of the right lung was suspected, but two days later the râles disappeared. The next day, auricular fibrillation was present, but the patient was improving. The temperature was normal and the pulse rate ranged from 80 to 95 beats each minute. Administration of compound solution of iodine was continued, 10 drops three times a day, and the patient was kept at complete rest.

By September 6, the basal metabolic rate was +13 per cent, the pulse rate was 76, the systolic blood pressure was 90 and the diastolic pressure, 50. When, on September 18, the basal metabolic rate was —4 per cent, the pulse rate 67, and the blood pressure 80 systolic and 38 diastolic, administration of compound solution of iodine was stopped.

Two days later, the patient was dismissed from the hospital. By September 23, the symptoms of hyperthyroidism had been completely checked, and on the following day, with a basal metabolic rate of +21 per cent, the patient was allowed to go home, with directions to return to the clinic in two weeks. She returned October 14, at which time her basal metabolic rate was found to be +13 per cent. She was advised to go home, not to take any medicine, and to return later.

November 18, the patient returned as requested. Examination revealed recurrence of the hyperthyroid condition since she had stopped taking compound solution of iodine. She had tremor, graded 2, and a basal metabolic rate of +29 per cent. Subtotal thyroidectomy was performed November 26. The pathologic report was of diffuse small colloid and fetal adenomas in a colloid thyroid gland. Parenchymatous hypertrophy was not found. Clinically, however, the case was definitely one of exophthalmic goiter.

By the middle of December there had been gradual diminution of toxic symptoms. The patient was dismissed and advised to take compound solution of iodine, 10 drops daily for ten weeks. March 10, 1927, her basal metabolic rate was —5 per cent. Symptoms of hyperthyroidism had completely disappeared. Tonsillectomy was performed uneventfully at this time.

STUDY OF A SERIES OF CASES

In 1927 there were only four cases in which major operations preceded thyroidectomy by a few weeks to a few months, and of this number, two were cases of exophthalmic goiter and two of toxic adenoma.

In one of the cases of exophthalmic goiter and in one of the cases of toxic adenoma, the complicating goiter was recognized preoperatively, but thyroidectomy was advisedly deferred (the patient receiving compound solution of iodine meanwhile) until after more necessary operations had been done. In the other two cases the postoperative reaction brought to light the hyperthyroid condition and the condition of these patients, too, was satisfactorily controlled by compound solution of iodine, and subtotal thyroidecetomy was performed later.

As an example of the type of case in which the two conditions are evident and thyroidectomy must be given a secondary place, I would cite a case in which there was a brachial arterial embolus of forty-eight hours' duration, and in which hyperthyroidism also was evident. The patient was hospitalized, compound solution of iodine was given and efforts were bent toward reestablishing collateral circulation. When these efforts failed, the arm was amputated on the eighth day, and the patient's postoperative progress was uneventful; there was no sign of thyroid crisis. Later, subtotal thyroidectomy was performed, and the pathologic report confirmed the clinical diagnosis of parenchymatous hypertrophy.

Because of the small number of cases in this group, it is unwise to draw conclusions. However, in forty-five cases, thyroidectomy for adenomatous goiter with hyperthyroidism preceded another major operation and in thirty-six cases thyroidectomy for exophthalmic goiter preceded another major operation. It is fair to ask whether it might not have been safe to reverse the order of procedure in these cases.

In order to answer such a question intelligently it is necessary to review, from the standpoint of risk and advantages, the cases of toxic goiter, exophthalmic goiter and adenomatous goiter in which thyroidectomy had been done as the preliminary measure.

The mortality of thyroidectomy for exophthalmic goiter and toxic adenoma uncomplicated by another condition for which operation was required averaged 0.76 per cent in 1927. There were no deaths as direct results of thyroidectomy being done as a measure preliminary to other operations. Although deaths occurred, one from bronchopneumonia following a two-stage Mikulicz operation for carcinoma of the colon and one from rupture into the peritoneum of a corio-epithelioma, they were not attributable to the primary thyroidectomy. Consequently, it can be considered that in a fairly representative group of cases of toxic goiter, preliminary thyroidectomy has not increased the risk, but, on the contrary, from the complications which it is known are likely to arise when preliminary thyroidectomy has not been considered, it tends to eliminate the toxemia of hyperthyroidism and thus to diminish the risk of future major operations. Therefore there should be little doubt as to the true value of the procedure.

Interesting facts developed in the course of perusal of these cases. Eighty-eight per cent of the patients were females; this explains the fact that there was a high proportion of gynecologic operations in this series. The average duration of symptoms of exophthalmic goiter was two and a half years; the average duration of other complicating symptoms was two and eight-tenths years. Here it is well to call attention to the fact that, although the average figures would indicate close relationship between the onset and duration of these coexisting conditions, this is found not to be true when the individual case is studied This, then, is an example of the false conclusions concerning particular groups of cases which might be reached from coincidental figures.

In the cases of toxic adenoma the average duration of symptoms of goiter was fifteen and three-fourths years, and the average duration of complicating symptoms was six years.

CONCLUSIONS

1. Generally speaking, thyroidectomy should be performed preliminary to other major operations when a toxic goiter (exophthalmic or adenomatous goiter with hyperthyroidism) coexists with another condition in which surgical intervention is required.

2. Should an acute condition arise, in which the judgment of the surgeon indicates that advantage would be gained by deferment of thyroidectomy, the importance of giving preoperatively compound solution of iodine as a prophylactic measure against thyroid crisis must not be overlooked.

3. Of the patients in whom hyperthyroidism coexists with another condition for which operation is required, about 88 per cent are females.

4. There is no causal relationship between the toxic goiter and the complicating disease.

INTRA-ABDOMINAL ABSCESS

REPORT OF CASES

P. E. Stangl, M.D.
St. Cloud, Minnesota

FIFTEEN years ago I was confronted with a nine-year-old girl intensely ill. She had been sick for two weeks beginning with pain in the lower right abdomen and vomiting. She recovered, but toward the end of the second week pain developed in the lower abdomen with loss of strength. Examination revealed a septic child, with a temperature of 101, pulse of 120, respiration of 20, and moderate tenderness in lower left abdomen. The abdomen was flat and not rigid. The urine was normal; the leukocyte count 32,000 on two occasions. Light percussion of the abdomen revealed a mass in the lower left quadrant close to Poupart's ligament. Rectal examination revealed a tender bulging mass on the left. A diagnosis of intra-peritoneal abscess was made and the abscess opened and drained, with complete recovery in three weeks. She has been well since and is the mother of three children. The abscess wall was made up of omentum, small bowel and parietal peritoneum of the anterior abdominal wall. The absence of any great amount of literature on the subject and the fact that forty-two cases of like nature have been encountered, prompted me to correlate a few of the facts and make this report.

Perforated appendicitis with a circumscribed peritonitis about the appendix or accompanied by a diffuse peritonitis forms a basis for every case in this report.

Secondary intra-abdominal abscesses are classified as intra-peritoneal and extra-peritoneal. The intra-peritoneal type appears in three locations as one or more solitary abscesses which may be connected with each other. The protective barriers of the intra-peritoneal space are the omentum, bowel mesenteries and the parietal peritoneum and these wall off the suppurative exudate to form an abscess either in the right or left lower quadrant or in the pelvis about the bladder. The omentum in diffuse peritonitis helps to produce a localization of the peritonitis and this takes place usually about the portal of entry in the lower right quadrant. The abscess however may be walled off on the right side and may consist of more than one circumscribed abscess as described above. These encapsulations, if not drained, either fuse and perforate the protective wall in from six to ten days reproducing a generalized peritonitis, or terminate as a fibrous peritonitis with resolution. Perforation of the bowel has been reported.

The extra-peritoneal type are found secondary to a circumscribed abscess about the head of the cecum and are most commonly found behind the cecum. These, if not drained, may extend behind the ascending colon to form a perinephritic abscess, or may continue upward, resulting in a subphrenic abscess. A right empyema occasionally completes the picture.

The cases under consideration comprise one or a combination of two, three or four of the above described localized abscesses.

Clinically these cases present themselves as perforating appendicitis with a diffuse peritonitis or localized peritonitis in the right lower quadrant. The stage of progress is determined by the number of days after the original onset. The secondary process appears either before or after the appendix is removed with drainage. In the usual case, drainage is followed by an abatement of the abdominal symptoms and then the case starts to go wrong on the sixth or seventh day with the appearance of an afternoon temperature and pulse rise. With the appearance of these hectic symptoms secondary abscesses should be looked for. The leukocyte count will increase from 13,000 to 30,000 and should be taken twice daily for two or three days and if it remains persistently high or increases, a secondary abscess is the usual finding. When the secondary symptoms appear about seven days after the original drainage, the insidious onset is more likely to indicate intra-peritoneal involvement, whereas a sudden ushering in with chills and fever is more apt to be extra-peritoneal.

Considerable stress should be placed on the rising leukocyte count, taken twice daily, and whenever present is almost positive indication of an active secondary process. In looking for the localization, the piano percussion of Murphy brings out the areas of induration more readily than the usual palpation or heavy percussion. Diagnostic puncture is always admissible and is the more practical and safe procedure when used extra-peritoneally.

The only confusing differential issue may be a stitch abscess about the wound which appears about the fifth day. Careful examination with spreading of the wound will usually settle the question.

Once the diagnosis is made, free incision and drainage affords the best results. These drainage wounds should be large and left open, as the practice of partially suturing them is not good technic and often defeats the purpose of thorough drainage. Conservative handling of the abscess wall especially within the peritoneal cavity is imperative, as a diffuse peritonitis may be reproduced.

Fowler's position should be maintained at all times.

The reaction of intra-peritoneal pus is more pronounced when the abscess wall contains small bowel. Whenever the abscess wall is made up of omentum, parietal peritoneum and loops of the ascending or descending colon, the protection is as complete as nature can make it and if the surgical drainage is done with reasonable care a prompt recovery is certain.

Case 1.—A male, aged 63, was taken suddenly ill with chills and fever and moderate pain just above the right iliac crest posteriorly. Examination made two days after onset revealed a temperature of 102, pulse 100, respiration 20, a normal urine and a white blood count of 18,000. A slightly tender indurated mass was made out above the right iliac crest posteriorly. Diagnostic puncture revealed pus and under local anesthesia incision in the right flank and drainage of a large abscess was made. He returned in sixteen months with the same condition and the same treatment was instituted. Two years later he had another recurrence and another opening was made in the right flank through which a perforated appendix was removed. This was all done without going through the peritoneum. This represents the typical extra-peritoneal type.

Case 2.—A male, aged 17, complained of pain in the lower abdomen for two weeks. He stated that he had lifted a heavy barrel of ice and vomited for three days following the supposed injury. He remained in bed the first week but the second week was up and about. Three days before examination he complained of painful urination. Examination revealed a rigid tender abdomen with the greatest tenderness over the region of the sigmoid. Rectal examination revealed a resistant tender mass in the lower left pelvis. Fluoroscopic examination revealed the barium in the rectum, which shot into the descending colon through a three-inch thread-like stream and filled the colon above. As the rectal pouch filled he complained of pain. His temperature at this time was 99, pulse 96, white blood count 13,000; the urine contained many pus cells. Diagnosis: secondary intra-peritoneal abscess of left lower quadrant. The abscess was opened and drained but the response was not good and on the sixth day after drainage an induration of the lower right quadrant with rigidity of right rectus was found. This was opened, drained and the appendix removed. The patient recovered.

Case 3.—Operation was performed on a female, aged 18, for a perforated appendix with localized right-sided abscess. Progress was good for six days, when hectic symptoms appeared. A retro-cecal abscess was opened through the right flank. Progress was again good for four days when the fever reappeared. The retro-cecal opening was enlarged and a deeper pocket was found and drained. Ten days later chills and fever appeared and the patiently was intensely ill. Two days later a diagnostic needle revealed a subphrenic abscess and this was drained extra-pleurally. Two weeks later a right empyema was drained with resection of a rib in the posterior axillary line. She survived the ordeal, and is now in good health.

In conclusion, intra-abdominal abscess as outlined here is the secondary result of perforated appendicitis with generalized or circumscribed peritonitis. It should be suspected whenever evidence of infection manifests itself following abatement of the general abdominal condition. The leukocyte count is paramount in deciding the presence of pus in the body and should be repeated twice daily when in doubt. John B. Murphy originated the piano percussion in this work.

I hope that my classification of intra- and extra-peritoneal abscess will assist in correlating a definite entity under the complications of perforated appendicitis.

CASE REPORTS

ALCOHOLIC POLYNEURITIS WITH CRANIAL NERVE INVOLVEMENT: KORSAKOW SYNDROME*

REPORT OF CASE

Gordon R. Kamman, M.D., F.A.C.P.
Saint Paul

According to Bruch,[1] reports of cranial nerve involvement are relatively rare in the literature of alcoholic polyneuritis. In them paralysis of the vagi and of the phrenic nerves is usually given as the cause of death. Other cranial nerves subject to degenerative processes in chronic alcoholism are the vestibular, acoustic, oculomotor, and optic. The involvement may be either central (nuclear degeneration) or peripheral (demyelinization, vacuolization, and granular degeneration of the nerve fibers). Because of the frequency with which mental changes accompany peripheral alcoholic neuritis, and also of the concomitant degenerative processes in the spinal cord, Campbell[2] said, as long ago as 1894, "Alcoholic polyneuritis can no longer be looked upon as restricted to an affection of the peripheral nerves." Along with cranial nerve involvement of peripheral or nuclear type, one may encounter the complex of an acute polioencephalitis.[3] I[4] reported such a case. It has been noted that patients with alcoholic ophthalmoplegia are particularly prone to the development of mental disturbances, especially of the Korsakow type. This report is that of a case in point.

L. E., male, single, aged 37, was admitted to the neurological service at the Ancker Hospital complaining of pain in the chest, blurred vision, difficulty in walking, and marked indecision. He was very confused, thought that he had just been discharged from the Army, and did not know just why he was in the hospital or who had sent him there. The family history was negative except for the fact that the father had committed suicide. The past history was negative except for a previous admission to the hospital for chronic alcoholism and delirium tremens.

The physical examination was grossly negative and all noteworthy findings were confined to the nervous system. The left pupil was slightly larger than the right and both reacted sluggishly to light and in accommodation. There was moderate congestion of both optic discs but the fundi were otherwise negative. Concerning the extraocular movements, convergence and movements upward and downward were normal. However, there was paralysis of lateral conjugate deviation to both right and left. In other words, the eyes seemed to be fixed in the mid-line as far as lateral movements were concerned, but that there was no paralysis of the internal recti is shown by the fact that convergence was normal. This indicates a nuclear or a supra-nuclear lesion. There also was a slight involvement of the left abducens nerve (inward rotation of left eye) and nystagmus was present vertically. There was a spontaneous rotary nystagmus present upon a few occasions.

The upper extremities as well as the abdominal and cremasteric reflexes were normal. The lower extremities showed absent knee and ankle jerks with diffuse impairment of touch and pain senses distally. There was no atrophy, no fibrillary twitchings, and no pathological reflexes were elicited. The knee-heel test showed bilateral ataxia, the patient walked with a wide base and had a positive Romberg.

The mental examination showed that the patient was completely disoriented. He thought that it was 1919, and that he just had been discharged from the army. There was marked flight of ideas with overproductivity and increased psychomotor activity. The patient was hallucinated, frequently interrupted the examiner with questions directed at imaginary people, and was very distractible. The prevailing mood seemed to be one of euphoria and there was definite clouding of the sensorium. Many of his remarks were totally irrelevant to the situation then present, *i.e.:* "Well, boys, let's knock those spots off the ceiling." "Break off a piece of candy, won't you?" "We will have to get off pretty soon, some of the boys only have a dollar left." "You saw that lady that just passed—she is a peach."

Because of the unequal and sluggish pupils, the absent knee and ankle jerks, the gait, the Romberg, and the mental condition, the admitting officer made a tentative diagnosis of tabo-paresis. However, blood and spinal fluid examinations were negative and on the following day when I first saw him, the patient admitted having drunk about a pint of moonshine daily for the preceding two months. Because of the negative serum findings and the alcoholic history we felt that the patient was suffering from an alcoholic psychosis with polyneuritis involving some of the cranial nerves as well as those of the lower extremities. During the first two or three days in the hospital he was fairly quiet, the nystagmus began to subside, and within a week all of the extraocular movements had returned to normal except for an occasional vertical nystagmus. There also was some return of the knee jerks, but the ankle jerks remained absent.

On the third day after admission, and in spite of the improvement in his organic signs, the patient became worse mentally. He began to get noisy at night, thought that there was a case of beer under his bed, and was very restless. At first this was present only at night, but about fourteen days after admission the patient began to act peculiarly also during the day, showing the characteristic signs of a Korsakow psychosis. When asked where he had been the previous day he would recite a detailed account of various fancied experiences. One morning he said that he had been down town the day before, bought a shirt for seventy-five cents and put it on while standing on top of a sewer pipe that evening. Once when a nurse was shampooing another patient's hair, he said, "I washed that guy's hair three times yesterday." Again, he said that he had been to a picture show and that everybody in the place had been killed. He then asked if most of the people taken out of the morgue really were dead. On another occasion a nurse asked him where his drinking cup was, and he said that he had left it in his other cell, that he had two rooms in the hospital and that he alternated, sleeping in each one every other night. The mental condition grew progressively worse, the patient became increasingly noisy during the day, would void in his drinking cup and say it tasted like tea, became irritable and destructive, and finally, on August 23, one month after admission, was transferred to the state hospital for the insane with a diagnosis of Korsakow's syndrome (Korsakow psychosis with polyneuritis).

---

*Presented before the Ramsey County Medical Society, St. Paul, November 24, 1930.

On October 31st I received a communication from Dr. George H. Freeman, superintendent of the hospital, stating that all of the patient's cranial nerves were normal except for a slight vertical and lateral nystagmus. He walked with a broad base, had a positive Romberg, and the ankle jerks still were absent. Mentally, the patient was less confused, his memory had improved considerably, he was correctly oriented for place and person, but was somewhat confused as to dates. He no longer confabulated.

The above case is similar to others of its kind reported in the literature but is submitted for its clinical interest and comparative rarity.

HEMOCHROMATOSIS OR BRONZED DIABETES*

REPORT OF CASE

H. A. Miller, B.S., M.D., and J. J. Heimark, M.A., M.D.
Fairmont, Minnesota

A male patient, J. E., forty-eight years old, came to the office January 18, 1930, complaining of weakness in the legs, weight loss, and dryness of the mouth. The patient was born near Fairmont, Minnesota. He was the proprietor of a grocery store, had been married sixteen years, and had no children.

The patient's parents were born in Scotland and came to America a married couple when about twenty-five years of age. The mother is still living and about eighty years old. She had enjoyed good health. Her skin is fair. The father was a carpenter and engineer by trade and was a robust well man until the last four years of his life, when he had repeated attacks of severe asthma, which caused his death at the age of sixty-four. His skin was rather dark. The couple had six children, all born alive, one girl and five boys.

The first child, the only girl, was born in Scotland. She was in good health until about fifty years of age, when she died following an operation for exophthalmic goiter. Her face and arms were darker in color in comparison with other girls in the neighborhood.

Two brothers died when small and the patient did not remember them, nor did he learn the causes of their deaths.

One brother, forty-six years old, appears darkly bronzed, in fact even more so than the patient herein reported. In casual conversation with this brother he states he has stomach trouble that has been diagnosed "liver disease."

The youngest brother is thirty-seven years old, and in good health. He has the fairest skin of them all.

The patient knew nothing about his grandparents on either side.

The patient had suffered no accidental injuries, nor had he undergone any surgical operations. As a youngster he had had mumps, chickenpox and whooping cough, and at the age of thirty-eight a mild attack of inflammatory rheumatism. In February, 1929, he had a serious attack of pneumonia. He denied venereal disease. There was no history of occupational poisoning. He, as well as his wife and friends, maintained that his previous habits had been good. He had never used alcoholic beverages to any extent in earlier life and certainly not in later life. He likewise at the first time we saw him was not using any patent medicine, drops, nor prescribed medicine. At that time he smoked about a package of cigarettes a day.

The present complaint, as previously stated, was weakness in the legs, weight loss and dryness in the mouth. It is an interesting fact that the patient would not have come for an examination even at this time had there not been pressure brought to bear on him not only by his wife but also by a business associate.

The patient was apparently in his usual good health until in February, 1929, when he was very low with an attack of pneumonia. He recovered and gradually regained his strength and former weight of 167 pounds and by late spring and early summer of 1929 was feeling as well as usual and returned to his store work.

Around the latter part of August and the first part of September, 1929, he began to observe he did not have the usual physical strength and endurance of former years, while his legs would grow especially tired by evening. In the morning he felt well rested and refreshed. By the first part of October, realizing he was not improving, he concluded that his physical weakness was possibly caused by absorption of poisonous material from extensively involved dental pyorrhea. In four different sittings he had fifteen teeth extracted. No complications followed and in due season he felt a little stronger, while his endurance was better the remainder of the fall and early winter of 1929.

---

*Presented by Dr. J. J. Heimark, at the annual meeting of the Southern Minnesota Medical Association at Mankato, Minnesota, August 25, 1930.

At the beginning of 1930, he weighed 140 pounds and was feeling fairly strong. But from this time until January 18, when we first saw him, he had lost in weight and was down to 122 pounds. During this same space of time he first noticed he was craving more fluids than normally and drank considerable milk and water throughout the daytime, but never at night, though he voided once to three times at night. There was no history of polyphagia. The bowels were regular once a day without the aid of laxatives and there was no diarrhea nor suspicious discharge from the bowels. He had no history of jaundice nor cardiac trouble. He had had no edema of the legs, no cough nor chest trouble. The weakness in the legs was not associated with any symptoms of anesthesia nor paresthesia. The legs became tired and weak when he was behind the counter waiting on customers. No other symptoms concerning the mouth and tongue were elicited outside of the complaint that they were dry. His wife had observed that from September, 1929, the patient's skin had become definitely and gradually a darker brown than at any previous time. He denied having any pain.

In the physical examination the most striking and evident thing immediately observed was the marked bronzing of the face, neck and hands in contrast to the rest of the body, which showed only moderate discoloration. The sclera showed no jaundice beyond a yellowish haze. A definite acetone odor was noticeable to his breath. All his teeth were out. The tongue was beefy red and dry, in fact his mouth was so dry his articulation was impaired. The tonsils were small and free. No discoloration was seen on the mucous membranes in the mouth. No sentinel nor suspicious glands were palpable anywhere. The face, arms and legs showed emaciation two, on a basis of four, with a flabby dry skin and considerable loss of subcutaneous fat with atony of the muscles. There was no enlargement of the thyroid. The heart was not enlarged, while the sounds were apparently of normal quality and no murmurs were heard. The lungs revealed no adventitious sounds. The abdomen was definitely enlarged, with the entire lower liver margin extending diagonally into the abdominal cavity, the margin reaching the navel. (The patient had not observed that his liver was enlarged.) The spleen was not palpable. Apparently there was no free abdominal fluid, and palpation of the rest of the abdomen showed nothing abnormal. There was no hernia, varicocele nor edema of the scrotum and legs.

Rectal examination revealed nothing of significance. Neurologically, no pathological reflexes were elicited nor abnormal cutaneous sensations detected. The blood pressure was 150/86. Temperature 97. Pulse 70. The urinalysis showed: sp. gr. 1.033, acid reaction, amber color, no sediment, no albumin, while Haines' solution was reduced with one drop of urine. Microscopically numerous white blood cells were present and only an occasional red blood cell; likewise numerous hyaline casts. The leukocyte count was 4,800, while the hemoglobin was 95 per cent (Dare). The blood sugar was 270 milligrams. *X*-ray of the stomach was negative. Fearing esophageal varices because of the enlarged liver, we refrained from passing a stomach tube to determine the gastric function. The blood and spinal fluid Wassermann was negative. The next day, January 19, Dr. Miller removed a piece of skin from the left side of the neck and this was forwarded to the pathology department of the Mayo Clinic, for examination for the presence of hemosiderin or iron pigment, as we suspected we were dealing with a patient ill with hemochromatosis or bronzed diabetes. February 1, 1930, we received the report on the skin sent to them, confirming our suspicion.

Since the introduction of insulin in the treatment of diabetes mellitus, it has been found that bronzed diabetes or hemochromatosis is one of several other diseases or pathological conditions that shows resistance to insulin. Root reports a case of bronzed diabetes of approximately one year's duration. This case required gradually increased doses of insulin throughout the year. However, he died in coma in spite of the administration of 1,680 units of insulin in twenty-four hours. Whether or not bronzed diabetic patients prove to be insulin-resistant in every case, I do not know.

This patient showed apparently no resistance to insulin, and did very nicely on a diet of approximately 85 carbohydrates, 65 protein, 160 fats and 30 units of insulin a day. He, however, gradually developed edema of the legs and finally abdominal ascites, that could be relieved only from time to time by abdominal paracentesis. He was tapped the first time May 3, 1930. He continued a downward course in spite of supportive medical treatment and expired June 24, 1930, with the picture of acute gastric hemorrhage, caused apparently by the rupture of gastric esophageal varices. The skin, especially during the last two months of life, became more and more pigmented until he was almost black at the time of his death. The sclera maintained about the same yellowish tinge as seen at the first examination.

The liver, spleen, kidney and specimens of lymphoid tissues were forwarded to the pathology departments of the University of Minnesota and the Mayo Clinic.

McCartney of the pathology department of the University sent us the following report:

> "The sections of the tissues sent show very characteristic appearances of hemochromatosis. The liver and lymph node show extremely large amounts of iron-containing pigment. The liver also shows cirrhosis. The spleen and kidney show pigmentation with an iron-staining pigment, but, in comparison with the liver and lymph nodes, only a small amount."

Habein, of the Mayo Clinic, forwarded the report on the tissues we sent him and the report shows:

> "Liver—marked cirrhosis with extensive iron pigmentation of the hepatic parenchyma and connective tissues."
>
> "Spleen—extensive fibrosis and iron pigmentation of capsule and to some extent of the connective tissue elements."
>
> "Lymph node—extensive iron pigmentation of the reticulum."
>
> "Kidney—iron pigmentation, slight, confined mostly to convoluted tubules."

> "The diagnosis of hemochromatosis with severe cirrhosis of the liver is confirmed. (Dr. Robertson has seen the slides and agrees.)"
>
> Signed: Dr. D. C. Beaver.

Added to the pathological reports of the tissues here given, should have been included the picture of the pancreas. But being allowed, only after several days pleading with the family, what I should call a "grab bag" post-mortem examination, the pancreatic gland was missed. What we thought was a piece of the pancreas proved to be under microscopic examination a lymph node. A pathological report on the pancreas would have been most interesting. A comparative study of the changes in the pancreas with those of the liver and other tissues might possibly have explained why this patient was a mild diabetic as well as non-resistant to insulin. Clinically this patient was outstanding as a cirrhosis of the liver and passed out of the picture as such. Was it possible that the liver and lymphatic systems, which showed the heavier deposits of iron pigment as compared to the kidney and spleen, were carrying the burden of the pathology and that the pancreas was even at the time of the patient's death only slightly affected?

Root in his article refers to Sheldon's findings in one case of hemochromatosis in which the picture was hepatic insufficiency with abdominal ascites without glycosuria and the pancreas showed only .55 per cent concentration of iron. Sheldon also found that in all his cases diabetes was present where the iron concentration exceeded 1.5 per cent.

Textbooks devote only a few passing remarks to hemochromatosis or bronzed diabetes, give a bad prognosis and then dismiss the subject by stating the condition is a very rare disease. In bringing up the subject with Professor Berglund, Chief of the Department of Medicine at the University of Minnesota, this winter, I became deeply impressed with his review of the subject. Berglund stated, among other views, that Joslin accepted the diagnosis of bronzed diabetes only when the patient showed resistance to insulin. Berglund, however, was not ready yet to accept this view.

Is hemochromatosis a constitutional disease manifesting itself late in life with faulty iron elimination? Is there then, from infancy, a continual, gradual retention of iron pigment that insidiously works its havoc and after forty years or more of destructive work finally presents itself in full-blown regalia as evidenced by bronzing of the skin, enlargement of the liver, glycosuria, weight loss and muscular weakness? The significance, if any, of the discoloration in the patient's father and sister, is only conjectural. However, the patient's forty-six year old brother is certainly very dark brown or bronzed. In fact, he is more pigmented than the patient was the first time we examined him. We saw this man possibly six or eight times from the last part of January until his brother died, June 24, and we could not help but comment on the striking similarity of the skin pigmentation of the two. The added interesting thing, too, is that he has been diagnosed "liver trouble," —broad as this term may be. That the brother has the same condition is probable and possible, and leads us to suspect that the etiology can be constitutional.

LARGE BENIGN MOLE OF THE SCALP

REPORT OF CASE

E. W. Humphrey, M.D.
Moorhead, Minnesota

The patient, a laborer, fifty-one years of age, was admitted to Moorhead Clinic September 20, 1930. According to his family history his mother and five brothers were alive and well, while his father had died from an attack of pneumonia and his sister had died during confinement.

The patient had had no illnesses except scarlet fever and rheumatism when he was fifteen. While still a small boy he noticed a swelling or lump over the occipital region of the head, which continued to grow until it practically covered the occipital region with a base about half the size of the tumor. This mass resembled a large cauliflower in appearance, having many crevices and fissures upon its surface. Upon squeezing the tumor a thick cheesy exudate could be pressed from the part squeezed.

General examination failed to show, aside from some dental caries, any further abnormality. Laboratory examination showed the urine normal and the blood Wassermann was negative.

Under general anesthesia and the application of a tourniquet, the patient was operated upon September 21, 1930. The large mass was dissected off down to the periosteum of the bone. Large vessels were ligated and two weeks later skin was taken from the thigh and grafted over the entire surface.

The dissected tumor was sent to Dr. E. T. Bell's laboratory, where it was diagnosed as a benign mole of unusual size, containing a large amount of fibrous tissue. It extended down below the level of the incision.

According to the pathologist's report further operation was not advisable, since some of these moles extend deeply into the tissue. The report also stated that this type of mole sometimes recurs after removal, which, of course, greatly alarms the patient, but that recurrence of a benign mole is not malignant.

A differential diagnosis of growths of the scalp is at times very complicated, since the condition may be due to a variety of ways in which it originates. Some of these growths give way to malignant degeneration, while others remain benign. Benign moles of the scalp must be distinguished from elephantiasis of the scalp, which is a chronic and sporadic disease of the skin and subcutaneous tissues. It is characterized by enlargement, deformity, lymphangitis, swelling, thickening, and more or less papillary growth.

Verruca digita is a formation of growth commonly observed on the scalp where clefts or digitations are sometimes found extending nearly down to the base. When the digitations do not extend completely to the base, the lower part or neck is sometimes relatively much smaller and the growth has then a pedunculated appearance, the upper cleft part tending to spread out somewhat.

Wens or sebaceous cysts of the scalp have little or no hairy covering. Ricker and Schwalbe in a monograph on tumors of the skin reviewed the literature up to 1914 and found that forty-three cases of malignant degeneration in sebaceous cysts had been reported. Of this number, the scalp was affected in but seven patients. Of 236 cases of sebaceous cysts excised at the Mayo Clinic only twelve were associated with malignancy and the scalp was involved only four times.

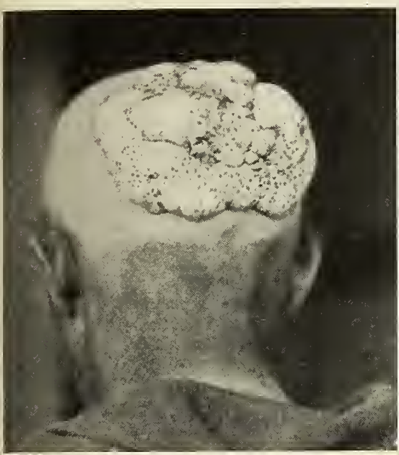

Fig. 1. Appearance before operation.

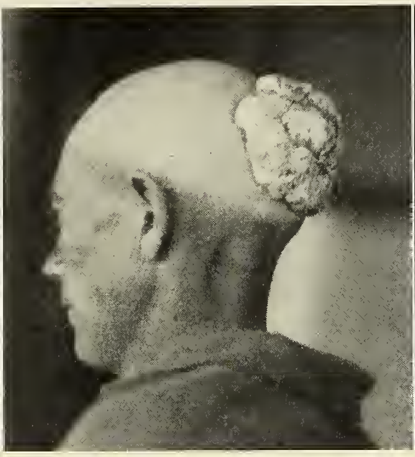

Fig. 2. Profile view before operation.

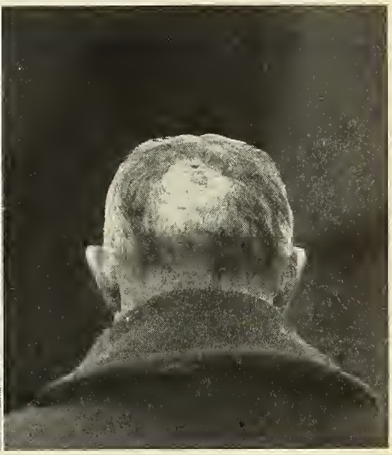

Fig. 3. Appearance six weeks following operation. Wound completely healed.

Cylindromatous tumors occur on the scalp, principally in women, as a lobulated growth covered with thin reddish blue skin, not spontaneously ulcerating and of long duration.

Nevus vasculosus is both flat and elevated from the angiomata proper, the former being histologically primary angiectases without any capillary budding. They are sometimes congenital and sometimes acquired.

According to Tieche of Berne, Switzerland, the two main charactertistics of nevi are the existence of the trouble from early life and the matter of their being benign.

A search through the literature in the Surgeon General's Library in Washington, D. C., has not revealed a case similar to the one here reported.

THERAPEUTIC POTENTIALITIES OF "MUSTARD GAS"

From time to time hopes are still entertained for some possible usefulness in medicine of "mustard gas," chemically known as dichlorethylsulphide. British and German investigators report that the dermal application of dichlorethylsulphide will prevent the development of the experimental cancer of tars. Forster of the Pharmacologic Institute at Würzberg has reported that dichlorethylsulphide in high dilution was the most efficient hair growth promoter of a considerable number of agents tried. Quantitative estimations of hair growth on shaved cats, treated locally with concentrations of 0.01 per cent of the compound in fifty per cent alcohol containing 2 per cent of glycerin, showed a much greater production of hair than with other substances used. Impure yellow petrolatum, but not the pure white product, was next in efficiency to dichlorethylsulphide, this being attributed to impurities acting as irritants. Forster found that when agents are used that cause excoriation a diminution or inhibition of hair growth occurs, and he suggests that this may also occur after injudicious application of dichlorethylsulphide. Lest the results of this research on hair tonics in felines arouse premature hopes in the bald and near-bald, it should be mentioned that not all shaved and bald skins responded equally well. Nor are all "war gases" necessarily effective, for the German cats, in Forster's hands, frankly declined to respond to the much vaunted "war gas" of the Allies. (Jour. A. M. A., January 3, 1931, p. 41.)

PRESIDENT'S LETTER

ANOTHER secretary's conference is over, with its crowded program and its multiplicity of problems pushing for attention in one short day's session.

It was particularly impressed upon me at this 1931 meeting that the great task of preaching public obligations to the doctors is all but done.

When such obligations are seriously discussed, not as fancy flights to be indulged in at meeting times only, but as the sober essentials of the business of the smallest county medical society, the fight is as good as won.

It is vastly significant for the future of medicine that societies of only fourteen members and less should be acting systematically and collectively to take an important part in the public health education and direction in their communities. Hitherto they have left such things for the most part to the state office or to the highly organized large city societies.

That this is the new pre-occupation of the smallest units of organized medicine was clearly in evidence at the meeting. To foster it is the most important single thing any man or group of men can do for legitimate medical practice and the public good.

Two practical and important contributions to the effective conduct of the doctors' collective business were submitted by the conference visitors from Wisconsin and Iowa. Without doubt the employment of full time executive secretaries for county medical societies of centers even smaller than Milwaukee is the next step in county medical society organization. I found Mr. Wiprud's account of the year's business, under his management in the Milwaukee County Medical Society, significant and valuable. Many of our Minnesota societies are headed in the Milwaukee direction. Equally important to the other people of the medical organization was the account of the enterprising and active little Polk County Medical Society, outlined by Mr. George Larson of Frederic, Wisconsin.

In Iowa the care of indigent institutional sick by contract with the county medical society concerned is a well oiled, well organized system. It has been working there for years. Vernon D. Blank of Des Moines, managing director of the Iowa State Medical society, and enthusiastic sponsor of the scheme, told Minnesota conferees he thought it would do equally well in Minnesota. The contract plan is an interesting and attractive possible solution to the problems of many of our Minnesota societies.

The degree of coöperation and interdependence between the State Medical Association and the public health agencies dispensing many thousands of dollars of volunteer funds in Minnesota, as reflected in the afternoon's symposium, was a surprise to nearly everybody. This practical working alliance between two frequently antagonistic agencies has grown up so quietly that even those of us who have been directly concerned have not appreciated its full extent and importance.

Our secretary, E. A. Meyerding, read a paper outlining its history and workings very fully before the secretaries' conference of the American Medical Association in Chicago this year. The subsequent expressions of astonishment and interest indicate the uniqueness of the arrangement.

I cannot do better in this letter than to urge every member of the association to read Dr. Meyerding's paper in the January number of the *American Medical Association Bulletin.* He is sure to share my pride in our association.

L. Sogge

President
Minnesota State Medical Association.

Vol. XIV March, 1931 No. 3

THE PSYCHOPATHIC HOSPITAL

The need of more adequate facilities for teaching psychiatry at the Medical School of the State University has been realized for some time by those who are acquainted with the situation. In the past about the only knowledge a medical student gained concerning mental diseases was obtained from a few theoretical lectures, a little reading and the occasional glimpse of a mental patient at one of the General Hospitals. On graduation he probably knew the definition of an hallucination, or an illusion, but of practical diagnosis and knowledge, almost nothing. The fault has not been with the teaching staff. They have done their best with time allotted and the facilities and material at their disposal. It has been due to the lack of a Psychopathic Hospital on the Medical Campus.

The importance of bedside teaching is readily recognized and admitted in surgery and medicine. It is no less important in psychiatry. Realizing this defect, a plan was evolved, and tried during the past two years, of having the classes spend three weeks at the State Asylums. This was not successful, on account of lack of teaching organization at the hospitals and the short space of time.

Aside from teaching, the purpose of the hospital would be to act as a receiving hospital for many patients from the country districts, who are now sent direct to the State Asylums. Many of these patients are there only a short time before recovering and would not have been committed had the facilities of observation and a short period of treatment been available. Such cases would be saved the stigma of a commitment. It would also assist the Probate Courts and physicians of the country districts in solving many difficult problems relative to commitment. In this way it would also act as a clearing hospital from the country districts to the State Asylums.

One of the objections to such a hospital is the cost. At present in the State of Minnesota there are approximately as many beds for mental cases as there are for all other hospital cases combined. Some of the hospitals have a waiting list and they all are reported crowded. The cost of such a hospital, whose main function would be to disseminate knowledge about diseases which have created such appalling conditions, is well worth while when the problem is viewed as a whole.

Another objection suggested is that it would be another step toward state medicine. It wouldn't even be a stagger in that direction when these 60 to 100 beds are considered in view of the fact that well over 5,000 mental beds are now maintained by the State.

Another objection suggested is that private institutions now treating such cases will be adversely affected. It is understood that the hospital will be conducted along the general lines now in force at the University Hospital. It will be a charity institution, but it is estimated that about 10 per cent admitted will be able to pay a part of their hospital expense. This situation now exists at the University Hospital. No private beds are contemplated. The experience at Colorado, where such a hospital is giving invaluable service, has been that worthy private institutions have been benefited by wider patronage by the public.

The situation will not be remedied until such a hospital is erected. It is earnestly hoped that the State Legislature will become cognizant of the problem and will heed the plea of the University for such a hospital on the Medical Campus.

George N. Ruhberg, M.D.

WORK AND HAPPINESS

The capitalist assisted by the economist wanders at times from his own domain into the field of medical economics. We plead guilty to the offense of getting out of our own field in making the following observations.

Hamilton Fish recently presented a report of his investigation of communism in the United States. According to the report, there is an active organization in this Country working under the direction of Russian communistic leaders whose purpose it is to undermine our American economic system. This is doubtless of serious import. It is, however, of additional interest to hear that in the same report Mr. Fish asserts that Capitalism is on trial in this Country.

There is some reason to believe that we, as a nation, are money-mad—that money is our standard of value. A millionaire dies and leaves all his wealth to his few immediate heirs, ignoring all of the many social activities devoted to the betterment of his fellowmen. Of course, he may have donated liberally to various activities of this sort during his lifetime, and that is admittedly the more worthy way of giving. But does such an exhibition *post mortem* tend to counteract the spread of communistic ideas?

Have capitalism and big business fully appreciated their responsibilities? No! and never will entirely.

The attitude of big business towards the employee varies in the extreme. One large concern we have in mind has developed an enviable reputation with the public and a devotion on the part of its employees. And why? Because somewhere at or near the top there is a someone who treats the employees as human beings and not simply as cogs in a soulless machine. Each employee is guaranteed a minimum hourly wage and a certain number of hours' work a week so that he knows what he can count on. Provision is made for an old age pension and employees are not discharged just before the pension age is reached.

Another large company we know something about is the exact antithesis of the above. Factories are closed unless they can be run at full capacity—it pays more. This results in periods of unemployment each year and the much vaunted high minimal daily wage amounts in a year's time to very poor pay. From the bottom up, employees are dismissed without consideration for length or quality of service rendered. Is there any wonder that there is little real esprit de corps in the organization?

Happiness is what we all are striving for. One achieves it in one way—one in another. On the whole (although there are those who would argue otherwise) work is one of the essentials for human happiness—work that is congenial and that brings the desired results. No one can be happy who fears the loss any moment of his livelihood. The anxiety incident to such a situation seems at times worse than actual unemployment itself. When an employee sees a total lack of consideration on the part of the employer for his employees as human beings, he is likely to despise his employer and hate his work. To him the whole world is wrong. Such a situation will often bring the employee to the verge of a nervous and mental collapse, as physicians have occasion to know.

So much for business methods in use in our Country in the twentieth century. Some argue that periods of more or less unemployment are necessary. Admittedly, some individuals are too lazy and useless ever to be entitled to a job. But such an extreme degree of unemployment as we are now experiencing should be preventable. The suffering entailed is much worse than that resulting from the so-called high cost of medical care. Whether the solution of the problem of preventing periods of financial depression lies in a revision of sales methods to prevent overproduction or abolishing the gold standard (a varying medium of exchange) and substituting a nonfluctuating governmental currency—here is a field for the energy of the business man and economist where there is a challenge.

HISTORY COMMITTEE

Will not some of you who read this "Historical Stuff" help to stimulate the gathering of material for our History of Medicine in Minnesota? Contribute something so we shall not have to think up new things from month to month to put in here. Our own knowledge of early medical men and events is largely confined to our own city and you may become tired of it. We long thought the first published medical communication came from a Minnesota physician in 1853, and Dr. J. H. Murphy contributed a note on abscess of the breast in 1854. A few months ago, however, we found an article written in 1815 and published in 1818 by the first medical officer at Fort Snelling, and a still shorter time ago we unexpectedly picked up Vol. I, No. 4 (January, 1859) of the *Minnesota Homeopath*, published in St. Paul. We had always thought Dr. A. J. Stevens' *Northwestern Medical and Surgical Journal* (1870-1874) the first in Minnesota. After looking over the *Homeopath*, however, we concluded it hardly merits the name of a journal, but nevertheless it gave us an historical, not hysterical, thrill. Write Dr. H. M. Workman, Tracy, Minnesota, if you know where any copies of the *Albert Lea Medical Journal* may be had. We would appreciate it.

J. M A.

OF GENERAL INTEREST

Dr. Sam E. Sweitzer and Dr. Henry E. Michelson were recently elected corresponding members of the Vienna Dermatological Society.

Dr. Stanley Chunn has disposed of his practice at Lake Wilson and is now located in Minneapolis, where he is taking a three-year fellowship at the University Hospital in the Department of Ophthalmology and Otolaryngology.

The Administration Committee of the University Medical School recently voted to use the terms Clinical Professor and Clinical Instructors in applying to faculty members giving voluntary part time service to the university. The distinction seems advisable.

Ground was broken Monday, February 16, for a new $200,000 nurses' home for Charles T. Miller Hospital, St. Paul.

The structure, which will be completed next fall, will be five stories, constructed of brick and reinforced concrete and fireproofed throughout. It will include dormitory facilities for 133 nurses and the hospital's nurses' training school.

Dr. Clay Ray Murray, Associate Professor of Surgery at Columbia University, New York City, visited Minneapolis at the invitation of the Minneapolis Surgical Society. Dr. Murray spoke on "General Treatment of Fractures" at the Hennepin County Medical Society Auditorium, February 4, and conducted a clinic on fractures at the Minneapolis General Hospital the day following. At the annual meeting and banquet of the Minneapolis Surgical Society held at the Nicollet Hotel, February 5, the society was addressed by Dr. Murray on "Delay and Non-union of Fractures."

Word has been received of the death of Dr. Charles Bryant Witherle, who practiced in St. Paul for a number of years. Dr. Witherle died at his home in Portland, Maine, February 3, 1931. He was born in Castine, Maine, on January 15, 1855, and received his medical education at Harvard Medical School, where he was graduated with the degree of M.D. in 1881.

Dr. Witherle moved to St. Paul the following year and practiced there for fifteen years. He was at one time associated with Dr. William Davis and afterwards with Dr. Alex J. Stone. He was for several years editor of the *Northwestern Lancet* and was at one time secretary of the Minnesota State Medical Association. After leaving St. Paul, Dr. Witherle went to Portland, Maine, where he occupied the chair of Professor of Nervous and Mental Diseases for several years, in the Medical Department of Bowdoin College.

The formal opening of the new quarters and library rooms of the Ramsey County Medical Society was held on Friday evening, February 27. Dr. O. W. Holcomb, president of the Society, made the opening address. Dr. John M. Armstrong spoke on the founding of the Society, and Dr. H. Longstreet Taylor gave a short history of the County Medical Society. An historical address was tendered by Dr. Alfred Brown, Associate Professor of Surgery at the University of Nebraska School of Medicine.

On Saturday morning, February 28, the occasion was also celebrated by clinics and demonstrations held at St. Joseph's Hospital by Dr. William Boyd, Professor of Pathology at the University of Manitoba, Winnipeg, Manitoba; Dr. Sumner L. Koch, Associate Professor of Surgery at the Northwestern University Medical School, Chicago; and Dr. Fred M. Smith, Professor of Medicine at the University of Iowa, Iowa City, Iowa.

A reception for members and ladies was held Saturday afternoon at the new rooms. Besides President and Mrs. Holcomb, there were included in the receiving line, Mrs. George Bell, daughter of Dr. John J. Dewey, a pioneer St. Paul physician; Mrs. Everton J. Abbott, daughter of Dr. John Steele, a founder of the Society; Mrs. Charles Eastwick Smith, Sr., wife of Dr. C. E. Smith, a founder of the Society; Mrs. John W. Willis, daughter of Dr. Alfred Wharton, a founder of the Society; Mrs. John F. Fulton and Mrs. Edouard Boeckmann.

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

"NON-MEDICAL INSURANCE"

Recently one hundred and fourteen life insurance companies in the United States and Canada reported favorably on their experience with non-medical life insurance in America. The report was given by the companies comprising the American Life Convention at St. Louis. It covered approximately ten years' experience with this type of non-medical business since a Canadian company made its first non-medical experiment, shortly after the Great War.

What is the significance of this radical change in insurance practice?

Dr. C. N. McCloud, Medical Director and Vice President of the Minnesota Mutual Life Insurance Company, of St. Paul, has the following comments to make:

> "The cursory, superficial insurance examination, ordinarily given by the insurance medical examiner, apparently bears no significant relation to the life prospects of the average healthy person under forty-five.
>
> "That being the case there is no good reason why insurance companies should pay the large added medical bill for these restricted cases. In the last two years in the United States and Canada, insurance companies saved approximately $9,000,000.00 in medical bills on their non-medical insurance business.
>
> "Naturally a physician's examination is necessary beyond the age of forty-five and wherever there is a question about the health of the prospect."

Dr. E. K. Geer, St. Paul, who handles a considerable amount of insurance work for several companies, agrees with Dr. McCloud that the usual brief insurance examination is of no great significance, either to the patient or to the insurance company. He says:

> "The favorable results reported by insurance companies with their non-medical business looks, on the face of it, like a rap at the medical profession.
>
> "It is really a rap at the usual insurance examination, that is usually required. A real physical examination, to elicit all of the truth about a patient, is expensive and requires time. It is seldom done for the small fee normally allowed by insurance companies for the purpose.
>
> "I am chiefly concerned with the effect that this reversal of insurance practice may have on the campaign for periodic health examinations for which they have been the most effective sponsors.
>
> "Will public health work in America be seriously retarded by this new turn in life insurance practice? It seems to me a serious question."

Non-medical insurance is written by agents who qualify for the privilege with their companies. It rests upon a keen layman's opinion of the general appearance of the prospect and the questionnaire concerning the history and heredity which he fills out. This report, is, of course, substantiated and checked with the confidential report provided by the effective detective service maintained by all life insurance companies.

It is written only for persons under forty-five and in some cases only for single women. In every case it is written only for small policies of not more than $2,500.00.

OBITUARY

Bernard Stanton Bohling

1887-1930

Bernard Stanton Bohling was born in Cumberland, Iowa, August 4, 1887. At the age of seven he moved to Lewis, Iowa, where he was graduated from High School. He then attended Northwestern University, where he received his medical degree in 1912.

After serving his internship he went to Sandstone, Minnesota, where he practised his chosen profession until his death, December 20, 1930.

On April 4, 1914, he was united in marriage to Miss Doris Barr at Chicago, who, with two uncles, are the only relatives left to mourn his untimely end.

He joined the Masonic Lodge before he came to Sandstone and was Worshipful Master of Sandstone Lodge 254 A. F. & A. M. for two years.

During the World War he saw service in France in the Medical Corps. He was a member of the Chisago-Pine and Minnesota State Medical Societies and a Fellow of the A. M. A.

Dr. Bohling was a man of outstanding ability in his chosen profession and will be greatly missed by his medical associates. Sandstone has lost one of her most valuable citizens, but his memory will long remain.

Dr. William Dodge

1856–1931

Dr. William Dodge died at his home in Los Angeles in January, 1931, at the age of seventy-three.

Born in Beetown, Wisconsin, on April 24, 1856, he spent his boyhood and received his early education there. In 1878, he was graduated from the Medical College of Keokuk, Iowa, and began practice at St. James, Minnesota. Four years later, he moved to Henderson, Minnesota, and after two years there, moved to Le Sueur in 1883. The same year, his first wife, Rose A. Simpson, passed away, leaving him two children, Laura and William Jr. In 1884 he married Lydia Smith of LeSueur. Two children, Alma and John, were born to them. After practicing four years in Le Sueur, at a time when practicing medicine was a rigorous occupation, he moved to California, where he has practiced in Los Angeles since. He was one of the organizers of the Los Angeles County Medical Society, and in 1893 was its president. In the early nineties, he was a devotee of horseback riding and owned a large stable of thoroughbreds. He was a founder and one of the presidents of the Los Angeles Riding Club.

Dr. Dodge was a descendant of a long line of physicians dating back to the Revolution. He was a member of the Hollenbeck Lodge of Masons, Al Malaikah Temple, and the Maccabees.

Shortly before his illness, he was the guest of honor at a meeting of the Los Angeles County Medical Society, and was presented with a gold medal in recognition of his services.

Besides his widow and four children, he is survived by two brothers, Dr. Frank Dodge, of Le Sueur, and John Dodge, of Woonsocket, South Dakota.

MISCELLANEOUS

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

MEXICAN "DOCTOR" SENTENCED TO WORKHOUSE

State of Minnesota vs. Fernandez

Averlino Fernandez, twenty-seven years of age, formerly of Monterey, Mexico, was sentenced to one year in the Workhouse in the City of St. Paul by the Honorable John W. Boerner, Judge of the District Court, on January 12, 1931, following the entering of a plea of guilty by the defendant to a charge of practicing healing without a Basic Science Certificate. Defendant had been in St. Paul about sixty days at the time of his arrest. He had no medical experience, but had worked in a drug store in Monterey, Mexico. He confined his practice to the Mexican people in St. Paul and South St. Paul. Judge Boerner informed the defendant that if a future complaint was made against him he would be placed in the Workhouse and made to serve the sentence without any opportunity of having a trial.

In addition to the splendid attitude displayed by the Court, Mr. Brist, representing the State Board of Medical Examiners, reports a fine spirit of coöperation received from Michael F. Kinkead, County Attorney, Thomas A. Brown, chief, St. Paul Police Department, Sheriff Moeller of Ramsey County and Sheriff Maher of Washington County.

APPELLANT IN BASIC SCIENCE LAW CASE PLEADS GUILTY

State of Minnesota vs. Broden

On Tuesday, December 16, 1930, A. H. Broden, the defendant in the above entitled action, entered a plea of guilty to practicing healing without a Basic Science Certificate in the District Court of Duluth. The Court imposed a fine of $25.00.

It will be recalled that Broden, following his arrest on a charge of practicing healing without a Basic Science Certificate took his case to the Supreme Court, where, on the tenth day of October, 1930, the law was upheld. Broden claimed to be a Naprapath. He has been residing in Superior, Wisconsin, for some time, and this fact, coupled with the large expenditure made by the defendant in the appeal of the case to the Supreme Court, undoubtedly occasioned the modest fine imposed. It has been reported that Broden's health has been failing for some time, and that he is at present under the care of a physician and surgeon. Mr. Brist, attorney for the State Board of Medical Examiners, was not present in Court when the case was disposed of on account of the failure of Mr. Forbes, the County Attorney, to notify Mr. Brist that the case would be disposed of on that day.

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., *Director*
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—I have under my care two men with chronic gonorrheal infections.

One, age 28, had infection for past five years, and has been under treatment intermittently for two years and constantly for past three months. During this latter period he has been treated twice a week with sounds up to F.32 followed by potassium permanganate irrigations of 1–5000 for three week periods and then prostatic massages twice a week for another three week period. Urine, glass No. 1, shows a very few shreds and is clear, and glass No. 2 shows one or two shreds occasionally and is clear. The mid-portion of the prostatic gland feels soft and examination of prostatic secretion under microscope shows fifty to sixty pus cells with a few clumps of four to six cells per high power field. He now has a small amount of watery secretion in the morning.

The reason for his taking treatment was a persistent ache at the base of the scrotum in the prostatic region. Since being under steady treatment, the patient states that at times this ache seems better and at other times worse; but there has not been constant steady improvement in this symptom.

The other patient, age 32 years, was treated from June to November, 1927, for a gonorrheal infection and discharged as cured. During that period he was treated with dilatations with a Kollman dilator followed by .25 to .5 protargol and was given prostatic massages. He remained symptom-free until in May, 1930, when he began to have an ache at the base of the scrotum in the prostatic region.

He was married about March, 1930. He has been treated since July, 1930, in the same manner as the other case which has been just described. Urine, glass No. 1 at the present time is clear with three to five shreds, and glass No. 2 clear with very occasionally one shred. Examination of prostatic secretion under the microscope shows the high power field loaded with pus cells, which are occasionally clumped. The prostate gland now feels slightly larger than normal and firm. There is no other symptom except the ache mentioned before, and he does not notice this very much when he is busy or occupied.

These two cases I have diagnosed as chronic gonorrheal prostatitis, but the treatment given them has not improved their subjective symptoms, and the examination of the prostatic secretion has not shown improvement.

Answer.—These two cases are similar and will be discussed together. Persistent ache in the perineum is the chief complaint in both. Gonorrheal urethritis was acquired five years ago in the first and three and one-half years ago in the second case. There has been no urethral discharge for many months except for an occasional watery drop in case one. Gonococci have not been demonstrable in either case for more than a year. Voided urines show glass No. 1 clear with a few shreds and glass No. 2 clear with no shreds. Microscopic examinations of the expressed prostatic secretions show large numbers of pus cells. Prolonged courses of treatment by prostatic massages, dilatations of the urethra and irrigations or injections have only temporarily benefited both.

Further investigation of these cases is advisable before considering future treatment. The anterior urethra should be examined for mural infiltrations and enlarged and tender littré glands by means of acorn exploratory bulbs and palpation over large sized sounds. The prostate and seminal vesicles are next investigated. These structures are best palpated bimanually. With the patient bent over and the elbows resting on the knees the examiner introduces the index finger of the right hand into the rectum well beyond the base of the prostate and the left hand is placed on the lower abdomen. By exerting pressure downward and inward with the left hand, the base of the bladder, the seminal vesicles and the prostate are brought down within easy reach of the examining finger. The size and consistency of the vesicles are noted and they are emptied of their contents by stripping with the finger. Palpation and massage of the prostate is then performed and the secretions are pushed downward into the anterior urethra and gathered on a slide for microscopic examination. The posterior urethra is examined for the presence of granulations with the urethroscope. Polyps, granulomata and lymphocystic bodies are not infrequently found in such cases and may entirely explain the symptoms complained of.

The results of these examinations will indicate the treatment. Mural infiltrations or enlarged tender littré glands of the anterior urethra are treated by full dilatation with sounds and massage over these instruments, followed by permanganate lavages. Prostatic massages should be continued in both cases and performed vigorously enough to thoroughly empty the gland of all inflammatory products. This is best accomplished by the bimanual method described. Infected seminal vesicles are emptied by stripping at the same time the prostate is massaged. The secretions from these structures are collected and examined microscopically to determine the progress of the case. Dilatation of the posterior urethra with the Kollman dilator to 35 or 36F should be occasionally done before massage. Each treatment is concluded by an antero-posterior injection of 2 per cent mercurochrome. Occasional cases of seminal vesiculitis are very resistant to treatment. Puncture of the vas and injection of the vesicles with protargol solutions has been tried in such cases but is of doubtful value. Hot rectal douches several times daily will hasten resolution in the prostate and seminal vesicles. Granulations of the posterior urethra are destroyed by fulguration or by topical applications of 20 per cent silver nitrate solution through the endoscope.

It should be possible to relieve each of these patients of the perineal ache complained of if

(Continued on page 271)

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association
Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and St. Paul (810 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of March will be as follows:

March 4—The Rheumatic Child
March 11—Treatment of Insomnia
March 18—Cause of Meningitis
March 25—Cancer of the Bladder

RICE COUNTY MEDICAL SOCIETY

The annual meeting of the Rice County Medical Society was held February 4 in the Main Building of the School for the Feeble Minded at Faribault, in conjunction with the Medical Auxiliary. Dinner was under the supervision of Dr. and Mrs. Murdoch and those present were entertained by the pupils of the school. The meeting was called to order by the president of the Society, Dr. J. M. Murdoch. Mrs. A. M. Hanson, president of the Auxilary, preceded Dr. Horace Newhart of Minneapolis, who spoke on the subject of "Mastoid Possibilities."

C. J. Plonske, *Secretary.*

WASHINGTON COUNTY MEDICAL SOCIETY

The Washington County Medical Society held its monthly meeting February 10, 1931.

After dinner the guest speaker, Dr. F. E. Burch of St. Paul, gave a very interesting illustrated lecture on "Strabismus." The doctor kindly answered a number of questions.

E. Sidney Boleyn, M.D.,
Secretary.

WEST CENTRAL AND KANDIYOHI-SWIFT SOCIETIES

The West Central and Kandiyohi-Swift County Medical Societies held a joint meeting at Benson, January 21, 1931. A banquet was served at the Congregational Church Parlors.

Mr. Marcus Shellander of St. Mary's Hospital, Minneapolis, gave a demonstration of laboratory methods which are of practical value to the general practitioner. Mr. F. A. Augustin presented some movie films being shown by the Petrolagar Laboratories.

C. L. Scofield, *Secretary.*

MINNESOTA RADIOLOGICAL SOCIETY

The midwinter meeting of the Minnesota Radiological Society was held February 14, 1931, at the Minnesota Club, St. Paul, Minnesota. The following program was presented:

Round Table Discussion of Cases of Diseases of the Bones and of the Thorax
Conducted by
Dr. R. G. Allison, Minneapolis

Round Table Discussion of Cases of Diseases of the Gallbladder and of the Gastrointestinal Tract
Conducted by
Dr. John D. Camp, Rochester

Roentgenologic Changes Seen in Cases in Boeck's Sarcoid and Related Lesions
Dr. S. A. Morton, Rochester

A Correlation of the Various Factors Involved in the Classification of Chronic Arthritis
Dr. M. J. Shapiro, Minneapolis

Pulmonary Metastases
Dr. Eugene T. Leddy, Rochester

The Medical Histories of Cases of Carcinoma of the Stomach
Dr. Jacob Sagel, Minneapolis

Leo G. Rigler, M.D., *Secretary.*

AMERICAN ASSOCIATION FOR THE STUDY OF GOITER

The American Association for the Study of Goiter will hold its meeting at Kansas City April 7, 8 and 9, 1931. The following Minnesota physicians appear on the program: Dr. H. S. Plummer, Rochester; Dr. J. F. McClendon, Minneapolis; Dr. Martin Nordland, Minneapolis; Dr. John Pemberton, Rochester; Dr. James Hayes, Minneapolis. The meeting will consist of clinics, symposia and addresses.

(Continued from page 270)

the investigations mentioned are made and the program of treatment followed. However, a small number of cases of prostatitis are incurable. In some of these cases there is no history of gonorrheal urethritis. In these cases the prostate is enlarged, boggy and riddled with small abscesses. Treatment is ineffective and often aggravates the symptoms, in which event it should be discontinued.

2. *Question.*—A young lady, age 25, consulted me in regard to what appears to be alopecia areata. The condition has existed for about six months, the symptoms being loss of hair in region of eyebrows and upper eyelids. There are some fine hairs and some short black stubby ones. Some hairs removed show a little enlarged condition. History and physical examination otherwise is negative. I have used the quartz light and prescribed ointment containing salicylic acid, sulphur and tar.

   Answer.—The diagnosis is probably alopecia areata. No known etiology has been demonstrated. All dermatologists advise rubifacients. Glandular therapy is without avail. Ultra-violet radiation at times does good. The prognosis is usually good, and psychotherapy should be directed along these lines.

WOMEN'S AUXILIARY
Minnesota State Medical Association

President—Mrs. S. S. Hesselgrave, St. Paul
Chairman Press and Publicity—Mrs. E. A. Meyerding, St. Paul
Editor—Mrs. A. A. Passer, Olivia

PANORAMIC VIEW OF THE WOMAN'S AUXILIARY TO THE A. M. A. IN FOUR ARTICLES

1. THE EASTERN DISTRICT

MRS. W. WAYNE BABCOCK

According to the Constitution of the National Auxiliary the First Vice-president is automatically chairman of organization, the three other Vice-presidents being organizers for their section of the country. Mrs. Southgate Leigh of Virginia, therefore, holds this chairmanship, and the Eastern District is her particular responsibility. At her request a series of four articles is being prepared by her committee in order that each district may be cognizant of the progress of its own state as well as those of the other three sections. The individual state journals have been generous in extreme in the space they have allowed their auxiliaries and this additional courtesy of reporting the auxiliary situation in other states is deeply appreciated, for there is a growing desire to know "what others are doing."

New Hampshire stands alone as the only New England state 100 per cent organized and coöperating with the National Organization. Last year the state auxiliary had misgivings as to its necessity and usefulness, but an urgent request from the medical society that the women remain organized, dispelled all doubts. During the year following, Mrs. Hubbard, wife of the State President, visited every county, which encouraged and stimulated the growth of unit auxiliaries.

The New Jersey Auxiliary made pilgrimages to state institutions, set apart one meeting when the mothers of physicians were entertained, and sponsored various health meetings. The Essex County Auxiliary, assisted by the physicians, succeeded in establishing a course of health talks, in coöperation with the Y. W. C. A. of Newark, emphasizing especially prenatal care and information which would aid the mothers of babies and young children. Last year Mrs. James Hunter, Jr., New Jersey's State President, visited every county, as did Mrs. Walter Jackson Freeman in Pennsylvania, during her Presidency. One cannot help drawing the conclusion that personal contacts are necessary for county development and success.

Virginia is active in spots. The doctors encourage the auxiliaries as they believe that through them education with regard to the menace of state medicine can be spread.

Ohio for several years has been sending representatives from a few organized counties to the National meetings, but as yet there is no state organization. As our friend and advisor, Dr. Upham, lives in Ohio, it is felt that he will advise the National Auxiliary when the auspicious time arrives for the establishment of a State Auxiliary.

The District of Columbia seems so completely diverted with Washington affairs that the auxiliary which so capably cared for the A. M. A. meeting some years back seems to have gone into retirement.

Delaware in a breathless, better-late-than-never manner, has completely caught up and is most interested and active and has entered upon serious work by assisting the men of the profession in establishing a medical library in Wilmington. They will coöperate with Philadelphia at the time of A. M. A. and the eastern section will introduce them with pride to the National Organization. West Virginia is up and doing and you may expect still better things from that State this year.

Maine, Massachusetts, Rhode Island, Vermont and Maryland have reported the interest of individuals but no organized effort. Queries from different localities in New York as to why there is no auxiliary have been answered with the statement that several years ago the House of Delegates voted unanimously in favor of the auxiliary and authorized its organization. The same year Connecticut voted favorably but no definite steps have been taken.

Pennsylvania has surely discovered the rhythm in which its auxiliary work is best done, for concrete accomplishments have been turned out regularly, year by year. Of the three thousand dollars contributed last year to the Medical Benevolence Fund more than two-thirds was contributed by the Auxiliary. A definite trend toward educational meetings is felt all over the state and socially it is hoped that the carefully formed Philadelphia plans for the next meeting will bring honor and glory to the Keystone State. Not only are the adult members of the auxiliary meeting, but a group of the most charming and good-looking daughters of doctors are working together in order that they may know each other and work in unison for the comfort and pleasure of the A. M. A. guests when they come to Philadelphia in May. Verily, who can question the wisdom of the auxiliary, when it brings about so much willing work in behalf of the medical men of the country?

The midwinter meeting of the Executive Board of the Women's Auxiliary was held in the Colonial Room of the Lowry Hotel, Friday, February sixth. Luncheon was served at 12 o'clock, and the meeting was called to order by the president, Mrs. S. S. Hesselgrave. There were twenty-eight members present. Dr. L. Sogge, president of the State Medical Association, was the speaker for the occasion. He stressed the importance of past medical legislation and of present pending bills which are of interest to the medical profession, and advised that the Auxiliary members keep posted on current legislation. During the business session reports were given by the state officers, county presidents, and chairmen of committees.

Mrs. J. M. Murdoch was appointed chairman of Hygeia. Arrangements for the entertainment of the guests were made by Mrs. H. T. Nippert and Mrs. P. Roy of St. Paul.

HENNEPIN COUNTY AUXILIARY

The Women's Auxiliary of Hennepin County recently gave $50 to Glen Lake Sanatorium for their library and also purchased a five dollar Christmas Seal Bond. The annual meeting was held January 28, at the Business Women's Club, Minneapolis. Among the revisions of the Constitution, which were adopted at this meeting, were a raise in dues from one to two dollars a year, and the changing of the date of the annual meeting from January to March, and also includes three new officers, namely, a president-elect, a parliamentarian, and a custodian.

Officers elected for 1931 are: President, Mrs. Martin Nordland, Robbinsdale; president-elect, Mrs. Hugh Tunstead; first vice president, Mrs. J. S. Reynolds; second vice president, Mrs. S. H. Baxter; recording secretary, Mrs. Fred Pratt; corresponding secretary, Mrs. Daniel Bessesen; treasurer, Mrs. G. G. Eitel; auditor, Mrs. E. T. Evans; parliamentarian, Mrs. W. J. Brynes. An Advisory Board for the Auxiliary was appointed by Dr. S. H. Baxter, president of the Hennepin County Medical Society, consisting of Dr. Rood Taylor, Dr. Theodore Sweetser, and Dr. Cecile Moriarity.

PARK REGION AUXILIARY

A business meeting was held in January, at the home of Mrs. W. L. Burnap, of Fergus Falls, followed by a social hour. It was voted to send $15 to the Otter Tail Sanatorium to be used as a revolving fund for their industrial work. Mrs. E. R. Saethre, of Alexandria; Mrs. F. H. Vail, of Henning, and Mrs. A. C. Baker, of Fergus Falls, were appointed to investigate future projects for the Auxiliary. Mrs. Theo. Satersmoen, of Pelican Rapids, was appointed a legislative member. Mrs. C. O. Estrem, of Fergus Falls, was elected president for 1931.

RAMSEY CONTY AUXILIARY

Mrs. H. O. Skinner, 2190 Princeton avenue, St. Paul, was hostess to the Women's Auxiliary to the Ramsey County Medical Society, at her home, Monday afternoon, January 26. In reviewing activities of the organization it was reported that more than $200 had been spent on philanthropic endeavors, the organizations benefited including the Jean Martin Brown Home; Shoe and Clothing Committee of the St. Paul Council of Parent-Teacher Association; Volunteers of America; Goodwill Industries; United Charities for Children at Christmas. The Auxiliary also provided fifteen dinners and sent jellies and jams to institutions as well as assisted with sewing and mending for the Gillette Hospital for Crippled Children at Phalen Park and the Children's Preventorium at Lake Owosso.

WRIGHT COUNTY AUXILIARY

Officers for the Wright County Auxiliary are: President, Mrs. J. J. Catlin, Buffalo, secretary-treasurer, Mrs. George Norris, Annandale. The regular meeting was held at Monticello, the twenty-ninth of January.

RICE COUNTY AUXILIARY

The Rice County Auxiliary was entertained in December at the home of the president, Mrs. A. M. Hanson, of Faribault. After the business session the members devoted their talents to the task of dressing twenty dolls and making art books. These dolls and books were presented to the St. Lucas hospital in Faribault and the City Hospital in Northfield. Plans were made to keep the children in the hospitals supplied with dolls and books.

In January four Auxiliary members were guests of the Ramsey County Auxiliary, at a regular meeting, in St. Paul. The February meeting was held at the home of Mrs. J. M. Murdoch.

PROCEEDINGS MINNESOTA ACADEMY OF MEDICINE

Meeting of January 14, 1931

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club, Wednesday evening, January fourteenth, 1931. Dinner was served at 7 o'clock, and the meeting was called to order by the president, Dr. J. S. Gilfillan, at 8 o'clock. There were forty-one members and one visitor present.

Minutes of the December meeting were read and approved.

The president appointed a committee, consisting of Dr. J. F. Fulton (chairman), and Drs. Geist and F. R. Wright, to draw up resolutions on the death of Dr. F. A. Dunsmoor.

Upon ballot the following men were elected as candidates to the Academy: Saint Paul, Dr. Max H. Hoffman, Dr. John F. Noble, Dr. Clayton K. Williams; Minneapolis, Dr. Moses Barron, Dr. Kenneth Bulkley; University, Dr. Irvine McQuarrie, Dr. O. H. Wangensteen.

Dr. Emil S. Geist (Minneapolis), retiring president, then read his Presidential Address, entitled, "The Intervertebral Disc." This was illustrated by numerous lantern slides. There was no discussion of the paper.

The meeting adjourned.

R. T. La Vake, M.D.,
Secretary.

KOTEX

Because of inquiries received in regard to the nature of the deodorant present in the widely advertised sanitary napkin, Kotex, the A. M. A. Chemical Laboratory examined the product. A specimen was labeled "Genuine Kotex Deodorized." An enclosed circular contained the statement: "Kotex is odor-proof. A mild, pure, safe antiseptic removes any danger of offense during the use of Kotex." The Laboratory found the Kotex pads to contain an amount of boric acid which is too small to be considered of value as a deodorant. (Jour. A. M. A., January 17, 1931, p. 193.)

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

Meeting of January 6, 1931

The regular monthly scientific meeting of the Minneapolis Surgical Society was held in the lounge of the Hennepin County Medical Society in the Medical Arts Building on Tuesday evening, January 6, 1931, at 8 o'clock.

The meeting was called to order by the President, Dr. A. T. Mann. There were twenty-five members and nine visitors present.

The President announced the Annual Meeting and Banquet which would be held on the evening of February 5th at the Nicollet Hotel.

The scientific program was as follows:

Dr. Ivar Sivertsen reported a cast of "Exophthalmic Goiter Complicated by Pregnancy."

A case of exophthalmic goiter complicated by the presence of a pregnancy is always interesting, especially in view of the divergence of opinion held by the profession. Gillharn stated that "a woman with exophthalmic goiter should not marry; if she marries, she should not become pregnant; if she becomes pregnant, she should be aborted." Strause, Falls, Mayo Clinic and Lahey Clinic have claimed there was no evidence that pregnancy influenced the course of exophthalmic goiter. Since the use of Lugol's solution became popular in 1923, preliminary ligation ceased to be used to any extent and the Mayo Clinic and Lahey Clinic find that patients with exophthalmic goiter, although pregnant, may be treated medically and surgically with no more risk than in the non-pregnant case. Many obstetricians prefer conservative treatment during pregnancy to be followed by surgery after delivery. In either case the effect on the newborn is the same—nil.

In support of the view that a patient with exophthalmic goiter becoming pregnant may be operated upon without injury to mother or child, the following case was presented:

No. 30762, Mrs. A. G. N., housewife, aged 39, born and raised in this vicinity, the mother of three children (the youngest of which was five), noted an enlargement of her neck about a year prior to her first visit to the clinic. She had noted in the last five months increasing nervousness, weakness, profuse perspiration with tachycardia and palpitation, loss of weight in spite of good food intake. There were no gastrointestinal symptoms. She had not menstruated for two months.

Her family history disclosed the fact that her father, mother, a brother and two sisters were living and all were well except her father, who had a cancer of the lip. She had always been in good health prior to the last year.

Examination on June 7, 1929, disclosed evident loss of weight, thyrotoxic appearance, an enlarged thyroid moderately soft with bruit present. The blood pressure was 160 systolic, 70 diastolic; temperature 98.6°; pulse 134; heart normal except for rapidity, lungs clear, abdomen normal, teeth and bones normal. The uterus was enlarged, cervix softened, adnexa normal. Hemoglobin was 80 to 85 per cent, R.B.C. 4,800,000, W. B. C. 8,400. The urine contained one plus sugar, a trace of albumin with a few white cells, epithelial cells and bacilli. Meinecke was negative.

Diagnoses were: (1) exophthalmic goiter; (2) pregnancy.

Hospitalization was recommended. The patient entered Fairview Hospital June 10, 1929. The basal metabolism was plus 74 per cent; and checked four days later was plus 76 per cent. She was placed on light diet, Lugol's solution min. 10, p. c., ice locally, and bromides. History was then elicited that the patient, while ambulant, took Lugol's solution seven weeks prior to admission to the hospital. The tremor subsided and the general condition improved so that Lugol's was discontinued after eleven days in the hospital. Four days later the right superior thyroid artery was ligated under novocaine, without distress. Four days later the left superior thyroid artery was ligated under gas anesthesia, without distress. Six days later Dr. S. R. Maxeiner was called in consultation, and reported as follows: "The patient was seen in consultation with Dr. Ivar Sivertsen at 5:45 p. m., July 5, 1929, at Fairview Hospital. The history and physical examination, as recorded by Dr. Sivertsen, and the hospital records were reviewed. The patient's general checkup of hyperthyroidism was made. The patient is running a pulse of 135 and the blood pressure is 135/60, with marked tremor, exophthalmos, and palpable thyroid. Pelvic examination was not made but Dr. Sivertsen states that the patient is more than four months pregnant. I agree absolutely that this is a case of exophthalmic goiter, and that surgery will be the natural treatment in her case. In spite of the fact that the patient is pregnant, the pregnancy is so early that we have no assurance that the patient will not abort and the pregnancy be naturally discontinued because of her thyrotoxic condition. As a result, I believe that the patient herself is the most to be considered in this particular instance and that surgery should be employed as soon as indicated. I would suggest that the patient be given large doses of Lugol's for a few days in an effort to slow the pulse and possibly put her in better condition for operation. If she does not respond to treatment, it may be necessary to resort to surgery in view of the fact that she is losing weight rapidly. (Signed) Dr. S. R. Maxeiner."

Eight days later, during which time weight loss and tachycardia had continued, a thyroidectomy was performed under novocaine and ethylene anesthesia. Her postoperative convalescence was uneventful. She sat up on the tenth day and left the hospital on the sixteenth day postoperative.

The laboratory diagnosis was toxic adenoma.

One month postoperative, the patient had increased in weight and strength and felt well; the pulse was 80, and the pregnancy undisturbed. Three months postoperative, the weight continued to increase, the blood pressure was 140/80, and the pregnancy o.k. Nine months postoperative, the patient reports that a normal baby was born five and one-half months postoperative. The delivery was normal, and conditions normal. Nineteen months postoperative, the patient's weight was 144 pounds (formerly 114 pounds), and she was well and healthy.

DISCUSSION

Dr. E. K. Green said that Dr. Sivertsen's case, with his modern up-to-date treatment, reminded him of a case which he had seen with the late Dr. L. A. Nippert about twenty-nine years ago. The patient was a woman about 40 years of age, with all the physical signs and symptoms of a marked Graves' disease, who had come to full term with nothing but symptomatic treatment. The exophthalmos was extreme; she had a large thyroid, very fast pulse, and was very nervous. The family was desperately poor and while Dr. Green gave the chloroform (in a small 10 × 12 bedroom) Dr. Nippert had delivered a perfectly normal baby that was stillborn because of a protracted difficult labor. Somewhat to their surprise, the patient made an uncomplicated recovery from the labor.

Dr. Green added that the patient has never had surgical interference and when he saw her about two years ago, while she was in rather poor health, she was able to get about and do her housework.

Dr. A. A. Zierold asked how a diagnosis of toxic adenoma could be made in the laboratory.

Dr. Martin Nordland was of the opinion that it is characteristic that pregnancy has a tendency to aggravate the usual toxic symptoms of the thyroid, and if this were toxic adenoma it would perhaps account for the high basal reading of 74. The incidence of toxic goiter in pregnancy, according to Mayo, is 0.6 per cent. Pregnancy usually lights up the symptoms of toxic goiter, and he recalled a case where these symptoms subsided and the patient got along relatively well after the pregnancy ceased.

Dr. J. M. Hayes asked if the basal metabolic rate had been checked up after delivery and, if so, what it was.

Dr. Sivertsen stated that he did not take it afterwards. As far as the laboratory diagnosis of toxic adenoma was concerned, which Dr. Zierold questioned, Dr. Sivertsen had not accepted that. His own diagnosis in the case was toxic goiter. As to pregnancy in goiter cases, it is known that pregnancy increases the metabolic rate and pregnancy increases the toxicity of the gland. Lahey's figures show only 0.4 per cent, while Mayo shows 0.6 per cent of hyperthyroidism in pregnancy.

Dr. A. T. Mann said, in relation to Dr. Zierold's comment, that if the laboratory men looked at the mass that was taken out and found an encapsulated mass they would feel that it was an adenoma.

Dr. Zierold said some one asked if this was a toxic adenoma or exophthalmic goiter. He felt there was no question about the accuracy of laboratory diagnosis of adenoma of the thyroid or of Graves' disease, but he did not know of any one yet who is able to make a diagnosis of toxic adenoma under the microscope.

Dr. R. C. Webb read a short paper and reported a case of "Hyperthyroidism Complicating Diabetes Mellitus" (to appear in MINNESOTA MEDICINE at a later date).

DISCUSSION

Dr. R. F. McGandy stated that he had heard two very interesting case reports this evening, but that he was just now interested in another phase of the subject and would appreciate an expression of opinion from Dr. Webb or Dr. Sivertsen (or any of the members) concerning, in particular, the causative factors in hyperthyroidism and whether or not one could justifiably say that nervousness or some emotional strain could cause hyperthyroidism. He was not referring to a preëxisting hyperthyroid which was aggravated by these factors, or to a preëxisting nervous system which the excitability may have precipitated. But he would like to have an expression as to whether one could say that some nervous shock, such as might follow an accident, could cause hyperthyroidism.

Dr. Webb suggested that several of the members present had had experience with hyperthyroid cases and if any of them had been associated with trauma he would like to hear of their cases.

Dr. Mann stated that it is well established in the literature, and all the men had been getting it in lectures for years, that shock is one of the manifestations of hyperthyroidism.

Dr. McGandy said this really was quite a question. He had recently seen three cases in which this had been a disputed point. While it was true that this had been taught as a cause of hyperthyroidism, Dr. McGandy felt that authors in recent years had been evading this phase, and only today he had read an article by a man who also seemed to evade the issue but placed nervous shock in the group of hereditary factors. Dr. McGandy would grant that an accident might precipitate the condition in one who had an inherently unstable nervous system; but could it do so in a person who is normal?

Dr. W. P. Herbst related some work which, however, was not conclusive because it was not completed. A man by the name of Duranti had made serial sections in the cervical sympathetics in exophthalmic goiter and reconstructed them in models. He was working on the theory that the amount of chromatin granules in the cervical sympathetics had something to do with exophthalmic goiter. On that basis one could figure out that shock might play a part in the production of exophthalmic goiter by the result of psychic shock on the sympathetic system.

Dr. Mann said that it is very definitely known that the chromaffin system, of which the cervical sympathetics are a part, has a very considerable influence on the activity of the thyroid gland. Dr. Mann was of the opinion that they were "begging the whole question." Of course if the person had no hyperactivity of the goiter before the shock and had it after the shock, then the shock would be the immediate cause of the upset in the whole complicated system which might have been started in some other way under other conditions.

Dr. Hayes said, in reference to Dr. McGandy's discussion of these cases in court, that it was usually pathetic and humiliating to the honest physician to go into court and tell what he knew about the cause of hyperthyroidism before a jury and an attorney who was attempting to discredit his testimony. No physician can honestly make a definite statement as to the factor injury or accident plays in these cases.

Dr. Nordland felt that the members were confusing the terms "cause" and "influence," as no one knows the cause of exophthalmic goiter. An accident might influence and cause an exacerbation of the symptoms of a toxic goiter in a patient who already has this disorder. He felt that the subject was getting highly theoretical when one considers the cause of thyroid disturbance. Boothby claims that in the average human being there is constantly about 10 mg. of thyroxin present and from 2 to 4 mg. of this is used up each day. Of course there is some mechanism present in the body by which this thyroxin is renewed. It has been considered that the center which controls the production of thyroxin may be somewhere in the brain. If this is true, it is theoretically possible for an accident to aggravate this central control of thyroxin production. Dr. Nordland felt that one could not talk with any degree of certainty about the "cause" of exophthalmic goiter.

Dr. Mann believed that this (the cause of exophthalmic goiter) comes from more than one direction; something which influences the pancreas, or the adrenals and the chromaffin system, or something which influences the gland itself can do it. Of course, the whole thing is under sympathetic nervous control more than anything else but this can be strongly influenced by cerebral impulses of certain types.

Dr. Webb stated he did not believe that hyperthyroidism could be atributed solely to an accident. The cause of this disease is not known but the present assumption is that a preëxisting state was present and that, given such a disease an influenza or other factors, the disease occurred as an exacerbation.

Dr. Arthur L. Herman read his Thesis entitled "Double Branchial Cysts Complicated with Carcinoma of the Larynx" (to appear in Minnesota Medicine at a later date).

DISCUSSION

Dr. James Johnson felt that this thesis was a very interesting one. It was particularly interesting to him since in 1926 he had read a paper on this subject before the State Medical Society in which he had reported five cases. None of them, however, were malignant. He stated the second and third branchial clefts were the ones in which there was most often embryologic defects and remnants. The second cleft, which empties into the tonsillar fossæ, and the third cleft, which enters into the pyriform fossa, were the two involved in Dr. Herman's case. Most often the cyst developed from the outer side of the cleft. However, in this particular instance it apparently developed from the ectoderm and pushed in through to the inside of the larynx. This is an exceedingly rare thing and especially to have such a remnant in this location malignant is indeed a rare situation. Dr. Johnson felt that Dr. Herman should be complimented on the care with which he prepared this case.

Dr. Hayes asked if Dr. Herman stated or had any definite figures as to the percentage of branchiogenetic cysts that had become malignant.

Dr. Mann said that of course the inner attachments of these branchial cysts or sinuses are always high in the neck because the mandible or lower jaw itself is in the first arch and the ear drum closes the first cleft, so it makes us jump to the second at least. The styloid process, the digastric muscle, and the little horn of the hyoid bone to which it runs are in the second arch, and the hyoid body and the greater wings of the hyoid are in the third arch, and the fourth (there is no fifth in the human) gives rise to all the structures of the neck below this. Sometimes one may find the cysts running deep but over the digastric muscle and styloid process when it arises from the second cleft, and running under the belly of the digastric muscle but over the great wing of the hyoid bone when it arises from the third cleft; and it is known that most of them arise from the second and third clefts. And, of course, with these solid growths there will be the question of dermoid inclusions, so when the tumors are of mixed cells they are spoken of as dermoids. Dr. Mann thought it was very rare to have two branchial cysts in the same person.

Dr. Nordland said that he did not understand the explanation Dr. Herman made for the loss of voice in this case. He believed that the pathology described was too high to affect the recurrent laryngeal nerve.

Dr. Herman stated that there were two cysts, one fairly high, but which might cause some pressure on the vagus at least. The other cyst was low enough to cause pressure on the inferior laryngeal nerve.

Dr. Nordland stated that he did not believe that pressure on the vagus alone would affect the voice.

Dr. Herman said that in this particular case the aphonia was much more apt to be due to pressure from the cyst within the larynx.

In answer to Dr. Johnson's question, Dr. Herman said that while he had no way of absolutely establishing the location of the cyst, he could only state in agreement with Dr. Phelps and Dr. Spratt, who had seen the patient, that the cyst was in the pyriform recess. The lower external cyst was also at this same level.

In answer to Dr. Hayes' question as to the percentage of branchial cysts which become malignant, Dr. Herman stated that this information was very difficult to obtain from the literature because of the fact that many authors undoubtedly included malignancies which did not have their origin in branchial cysts. Thus some authors included cases which were mixed tumors of the parotid. Others included cases where the possibility of an overlooked primary lesion in the nasal sinuses or larynx had not been properly ruled out.

In this connection he mentioned a case that was thought to be a malignancy of a branchial cyst, whereas at autopsy the primary lesion was found to be a minute carcinoma in the larynx. In other cases the primary lesions were found in the nasal sinuses. If autopsies had not been performed on these cases, they would have gone into the literature as branchiogenic malignancies. So, both because of failure of all cases to be autopsied, and because of lack of agreement as to just what constitutes a branchiogenic tumor, the figures in the literature are too high.

Dr. Mann asked Dr. Herman when the diagnosis of carcinoma was first made; whether it was on the first biopsy.

Dr. Herman said it was not made until the second biopsy.

Dr. Mann asked as to the type of carcinoma.

Dr. Herman stated that it was squamous cell.

Dr. Martin Nordland read a paper, illustrated with lantern slides, entitled "Increased Susceptibility of the Hyperthyroid Patient to Air Embolism, with experimental evidence."

DISCUSSION

Dr. Zierold felt that every one present would agree that this was a most excellent piece of work that Dr. Nordland had done and that he should be extended the appreciation and thanks of the members for bringing it before the Society tonight. He felt that it was an unusual observation, and that it was interesting to note how Dr. Nordland's observations conform to what are apparently unrelated observations on thyroid patients. He thought probably an extension of the series might do away with the false impression created by the record of the last animal in the experiments, as the curves all seemed regular up to that point.

Dr. Zierold called attention to the fact that the pulse pressure in the animals increased with the increase of dosage of thyroprotein; that, of course, conforming to clinical observations in hyperthyroidism. He also mentioned an interesting observtion of the end-results in hyperthyroidism noted by Dr. E. T. Bell. Recently he had examined at autopsy an untreated case of exophthalmic goiter, the only unusual finding being a generalized hypertrophy of the heart—apparently the same picture found in the other extreme, which is myxedema. Dr. Zierold stated that the premise on which Dr. Nordland's work is based is very clear. It would seem from the recent studies that there is a weakened heart muscle in the later stages of hyperthyroidism. If that is the case, Dr. Zierold felt that any mechanical disturbance, such as air embolism, interfering with the function of such a heart would cause the death of the animal sooner; and this is in accord with Dr. Nordland's findings.

There was one suggestion which Dr. Zierold said he might offer which might add to the accuracy of the observations, and that is to obtain the weight of the heart; checking the amount of air in proportion to the weight of the heart, as being a truer measure rather than the weight of the dogs.

Dr. E. A. Regnier asked Dr. Nordland whether or not he had noticed any embolic changes in the coronary vessels of the heart, and mentioned recent work by Rukstinat (Jour. A. M. A., Vol. 96, No. 1, Jan. 3, 1931), whereby he had injected air into the coronary arteries of dogs, with postmortem findings similar to those found by Dr. Nordland. Dr. Nordland mentioned that death seemed to be due to a mechanical obstruction of blood flow to the right heart; and Dr. Regnier felt there was a possibility that embolism of the coronary vessels may have been brought about by his procedures.

Dr. Johnson asked how rapidly this air was injected; whether it was injected slowly, or a given amount of air was injected in a given length of time.

Dr. Leo Murphy asked how often in their experience the members had seen air emboli. He had read about it (particularly in the foreign literature) and had heard about it, but he had never seen it, and was interested to know how many of those present had had any experience with air embolism.

Dr. Mann stated that he had never seen one. There had been a good many operations at the Boston Hospital when he was house surgeon but he had never seen one there nor in private practice. In connection with Dr. Murphy's remark about seeing more of them reported in the foreign literature, Dr. Mann stated that might be due, partially at least, to their method of operating; and then they have much larger goiters as a rule.

Dr. W. A. Hanson said that in reviewing the literature of thyroidectomies, air embolism has occurred few times in this country. Probably cases have occurred which were not recognized as such. Dr. J. Pemberton, in a review of the cases at the Mayo Clinic to 1924, states there was probably one case of air embolism which was recognized at the time of operation in 14,911 resections, and with only three deaths recognized to be due to pulmonary embolism.

Dr. E. T. Evans said that when speaking of "air embolism," one must remember that a good deal of air can be put into the jugular without causing death.

Dr. Webb wondered if among the large number of cases mentioned there were any that died during or shortly after operation and, if so, were they autopsied? He himself had had one case in which he would never have known the cause of death had he not succeeded in getting an autopsy. Dr. Webb was of the impression that there must be a definite condition present in or about the vein which has been cut to permit the air to enter and that this was a very important factor. He recalled a man he had picked up while riding the ambulance in New York. This man, while inebriated, had cut his throat and was lying in a pool of blood trying to sing, with a partially severed trachea.

Dr. Webb thought it would be interesting to know just how toxic Dr. Nordland's dogs had become. He also thought that to render the condition comparable to a patient undergoing operation, the dogs should be fed Lugol's solution and brought back to normal. It would rather seem that a heart which was being whipped on by a toxic goiter was better able to take care of itself under such circumstances than a normal heart. This is especially brought to our attention when one considers the large number of goiter operations performed with an inexperienced assistant catching the bleeding vessels.

Dr. Kenneth Bulkley said he was impressed by what Dr. Murphy said in regard to looking over the literature and the more frequent occurrence of emboli in foreign countries than in this country. Dr. Bulkley said he was in France two and a half years and watched particularly Morestin, who was the best known neck and facial man France had ever produced. Theoretically, Morestin should never have had an air embolism. He operated in a well of blood about two inches deep, had one non-sterile nun and usually only one 12- or 14-year-old boy helping him. He would do a block neck dissection in fifteen or twenty minutes. Dr. Bulkley had seen him do an excision of the tongue and neck dissection in a half-hour.

As to what Dr. Webb said about cut-throats and why they do not get air embolism, Dr. Bulkley stated that he had never seen a case and yet while he was house surgeon at Presbyterian Hospital in New York he was called when two of their old orderlies in a state of depression had cut their throats and neither had air embolism. He had seen two others but neither of them had had air embolism, although there were two immediate deaths in the group, one from immediate hemorrhage and the other later from sepsis.

Dr. Nordland (in closing) stated he wanted to thank the gentlemen for their remarks in the discussions. He appreciated Dr. Zierold's suggestion that the weight of the heart ought to be considered with reference to the effect of the quantity of air that might be injected.

Dr. Nordland believed that the reason why accidental injuries to the veins of the neck, such as cut throats, did not produce air emboli, was due to the fact that these veins were probably cut above the point where they passed through the fascia obliquely. It also might be explained by the facts demonstrated in this study, that it takes larger quantities of air to cause death in the non-toxic individual.

In answer to Dr. Johnson's question with reference to the rapidity of the injection of air, Dr. Nordland said the air was injected at a speed of about 100 c.c. within 2 seconds. The same speed was used for the normal and the toxic animals.

Dr. Murphy's suggestion that reports of death from air embolism were more common in Europe than in this country, might be explained by the fact that, in the past, postmortems were more frequent there than in this country.

Dr. Nordland wished to emphasize again that the object of this experimental work was to find out whether or not the toxic goiter patient was more susceptible to air embolism than the non-toxic patient, and he felt that from the results of this work one could say that the toxic patient was more susceptible.

An Eastman moving picture film of "Simple Goiter" was shown, after which the meeting adjourned.

H. O. McPheeters, M. D.,
Secretary.

PROCEEDINGS OF THE MINNEAPOLIS CLINICAL CLUB

Meeting of December 16, 1930

The Minneapolis Clinical Club had been invited by the St. Cloud Physicians to give their monthly scientific program at the monthly Staff Meeting of the St. Cloud Hospital, which was to be held at the Hospital in St. Cloud on the evening of December 16, 1930.

A bus was chartered and twenty members of the Clinical Club made the trip, arriving at the Hospital for a 6:30 dinner as guests of the Staff. After dinner the doctors adjourned to the Staff Room, where the meeting was called to order by their President, Dr. J. P. McDowell. After a cordial welcome, Dr. McDowell asked the staff members to rise as he called their names, introducing them to the members of the Clinical Club. He then called on Dr. Barron to conduct the meeting, first introducing the members of the Club.

Dr. Moses Barron: It is a pleasure to be here again. I was here once before and enjoyed it so much that I wanted to come again, and we thank you for your kind invitation to come down here and give this program.

The Minneapolis Clinical Club was organized ten years ago for the purpose of giving the younger men an opportunity to get together and meet in a social way to discuss rather informally various subjects in the different specialties. It is composed of the younger men; in fact, our Constitution states that only the younger men may belong. We have 33 members and meet once a month, and this meeting tonight is typical of one of our regular monthly meetings so that you may see just what they are like.

The scientific program consisted of the following papers:

Dr. J. M. Hayes read a paper on "The Treatment of Acute Empyema of the Gallbladder." (Paper not yet published.)

DISCUSSION

Dr. S. R. Maxeiner: I am very much interested in the report of Dr. Hayes' cases, and would have liked very much to have had an opportunity to look up my own records before discussing this paper.

I believe there are perfectly legitimate grounds in this field for differences of opinion and that a lot of these differences of opinion will be based on personal experience, often to the extent of "burnt fingers." During six years of service as surgeon at the Minneapolis General Hospital and approximately eight years of service as consultant for the Government, and in my private practice, I have had occasion to see a good many acute gallbladders and have personally come to the conclusion that, when it is possible to do so, the acute attack should be allowed to subside and the patient instructed to return for subsequent operation when the infection has entirely disappeared. In some instances, however, because the patients did not do well, we have been compelled to treat them surgically, and practically always by drainage rather than by removal of the gallbladder. Following an experience several years ago in which three cases of acute empyema with gangrenous gallbladders died following cholecystectomy, I swung completely to drainage of the gallbladder and since that time have not lost one single acute gallbladder that I have been compelled to operate upon. In the last two or three years, I have operated upon three perforated gallbladders, all of which formed localized abscesses. In these, the abscesses were drained and the stones removed without getting inside the general peritoneal cavity.

Recently, in a conversation with Meyer of Chicago, I find that his experience checks almost directly with my own and in comparing his cases with some of his colleagues who were operating upon acute gallbladders he was convinced that he was following the right plan. Ravdin, of the University of Pennsylvania, at the last meeting of the American College of Surgeons, reviewed their statistics and stated that their mortality was much higher with cholecystectomy than with cholecystostomy in acute gallbladders and that, even though 30 per cent of the drainage cases must return for cholecystectomy, the mortality from the double operation was lower than for removal of the gallbladder during the acute attack. I do not believe that it is possible to differentiate the gallbladder containing pus (empyema) from the severely acute gallbladder that may not be classed as purulent.

Dr. Hayes' findings and his subsequent cases are deserving of close observation and certainly we are all looking for an opportunity to improve our present methods. As for my own experience, I am basing my conservatism on my own lower mortality in conservative treatment of the acute gallbladder.

Dr. O. J. Campbell: I had my fingers burned in the other direction. I was called to see the father of a medical student because of two recent attacks of acute gallbladder disease. He was just recovering from an attack, so we deferred operation. Local tenderness had disappeared and we were on the point of operating, when I was called out of town for two weeks. I advised the student to have another surgeon operate. Returning, I found the patient had waited but was in the midst of another attack. Again we waited for the acuteness to subside but, because of the frequent attacks, feared to defer operation until he had fully recovered.

At operation we found a badly diseased, almost gangrenous gallbladder containing large stones. The common duct was not distended but the pancreas was enlarged and indurated. There was no fat necrosis. I removed the gallbladder feeling that it was too badly diseased to use for drainage. The patient, after an initial rally, died of acute pancreatitis and peritonitis on the tenth day. Extensive fat necrosis was revealed post mortem.

This illustrates to me the fact that in acute cholecystitis we are confronted with a situation where fine surgical judgment is required. We cannot sit tight on all cases, neither should we dogmatically operate all. In the case just cited, had the man been operated when first seen he might have escaped pancreatitis and death.

From the information at hand it is difficult to be sure of what constitutes a conservative attitude. For my own part, conservatism seems to dictate a policy of waiting when the onset is not too stormy nor the attacks too rapidly following each other. When the attack is extremely violent with evidence of rather widespread peritoneal involvement it seems wise to operate. Whether or not the gallbladder is to be removed depends upon the exposed pathology, the age and general resistance of the patient. Where there is no actual abscess surrounding the gallbladder it can apparently be safely removed. In very elderly people, debilitated individuals, and those in whom collections of pus have already gathered outside the gallbladder, conservatism seems to indicate drainage rather than excision.

There is a point in technic which is possibly worth recalling. In dealing with the friable cystic duct, not infrequently the cystic artery becomes loose. Trying to clamp blindly in a well of blood is very dangerous. A finger slipped through the foramen of Winslow will allow the hepatic artery to be compressed between thumb and finger while the blood is sponged out and the artery secured with forceps.

Dr. R. C. Webb: I think the proper word was mentioned when Dr. Campbell said that judgment should be used in acute cholecystitis. I feel that acute inflammation of the gallbladder is a serious condition and a definite rule should not be formulated for such patients as to whether one should permit the disease to subside or as to routine surgical intervention. When a patient has acute cholecystitis the surgeon should ask himself why he should *not* operate. There may be several reasons for not operating, *i.e.,* the disease may be subsiding or there may be other existing diseases in which an operation might create a hazard equal to that of acute cholecystitis.

In October of this year a patient was referred to me suffering severely from an exophthalmic goiter. She could be diagnosed at a glance at some distance and her basal metabolism was 55. On October 6 I performed a partial thyroidectomy and her recovery was very rapid. On October 12 she developed an acute inflammation of the gallbladder and the necessity of a second major operation became apparent and was seriously discussed. I felt that, inasmuch as she had just been through several weeks of hyperthyroidism combined with an operation for goiter, I had a reason for delaying operation. On October 22, however, she had nearly recovered from the goiter operation and the acute gallbladder was not improving so a laparotomy was made. The gallbladder was found full of pus with gallstones and there was a yellow necrotic area on the fundus the size of a twenty-five cent piece where it was about to rupture. The gallbladder was aspirated through this area and a cholecystostomy was performed through a stab wound and she made an uneventful recovery. This patient's record illustrated clearly the dangers in waiting.

In operating upon the acutely inflamed gallbladder a cholecystectomy is ideal treatment, but the conditions vary so much at operation that such a procedure may not be consistent with the life of the patient and a partial cholecystectomy or a cholecystostomy may be all that is possible.

I believe that our policy should be to use surgical judgment, to ask ourselves why we should *not* operate and, when we do operate, to perform an operation that will give us a live patient.

Dr. Hayes (in closing): I did not expect all the surgeons to agree with me on this subject. I never saw a group that did agree on it. However, as has been mentioned, surgical judgment is an important factor. One can usually have some idea as to how much the infection is confined to the gallbladder from the general appearance of the tissues. If the infection has manifestly spread to neighboring tissues and pus and necrotic tissue are present outside the gallbladder, this operation would not be advisable.

In these cases where we have the stone in the pelvis of the gallbladder or close to it and a very evident pressure on the cystic artery, we are quite sure gangrene will result if the process is allowed to advance. This is the case in which I am advocating a cholecystecomy as soon as it can be done. Much of the discussion has not been on this type of case. If you will review the literature closely on this type of case you may plainly see that this condition carries with it a large mortality. If it can be operated very early while the severe infection is still confined to the gallbladder and care is taken to prevent the spreading of the infection, the results are no doubt far preferable to those obtained by waiting.

Dr. E. S. Platou presented a paper (read by Dr. H. B. Hannah) entitled "Poliomyelitis; An Evaluation of our Present Methods of Treatment." (Published in Journal-Lancet, Feb. 22, 1931.)

ABSTRACT OF DR. PLATOU'S PAPER

Poliomyelitis undoubtedly is far more prevalent than is indicated by recognizable forms of the disease, having an age distribution of incidence corresponding somewhat to that of measles and diphtheria, and bearing a rather direct relationship to the density of population.

The serums of convalescents, adult contacts and of the majority of "normal" adults have verucidal properties, indicating that immunity to the disease is rather general, particularly in adults, resulting from recognized and more frequently from unrecognized forms of infection by the polio virus.

The possibilities of effective serum therapy point most favorably at present to the use of convalescent, adult contact, and "normal" adult blood serums. At present the convalescent serum seems to be the serum of choice in the early treatment of poliomyelitis although there is some evidence that adult contact serum may be even more valuable. Should further study demonstrate adult contact and "normal" adult serums to equal or exceed convalescent serum in effectiveness we will imediately be provided with an immense reservoir of anti-poliomyelitis serum for therapeutic use.

If convalescent serum is not available, the blood or serum of adults (preferably contacts) probably will serve as a valuable prophylactic agent.

DISCUSSION

Dr. Barron: We sometimes see sporadic cases of this disease even if it is not present in epidemic form, and I think that we should have quite a general discussion of this paper.

Dr. H. B. Hannah: I would like to add a few words in regard to the early diagnosis of poliomyelitis. A child that comes down with headache, vomiting, some fever, pain in a group of muscles, stiffness of the neck, et cetera, should be looked upon as a possible case of poliomyelitis or beginning meningitis. Early spinal puncture will in many instances make the diagnosis for us. In ordinary poliomyelitis there is not so much stiffness of the neck. I saw a patient several years ago with Dr. Platou and there was a question as to whether it was meningococcic meningitis or poliomyelitis. We decided the child should have convalescent serum. The disease finally turned out as meningitis, but which we were waiting there might have developed symptoms of poliomyelities. In other words, giving poliomyelitis serum does no harm, even if the disease is not present.

Another point is that poliomyelitis is a lower motor neuron lesion and very early the patient will show reflex disturbances, and some muscle or group of muscles in the body become paralyzed, so it behooves every man to go over the body carefully to determine whether there is any weakness anywhere in the body. And convalescent serum should be given, or adult serum used, as early as possible. If given later it is not nearly so effective as if given in the first twenty-four hours.

Dr. G. E. Sherwood (Kimball): I would like to ask what one should do for these patients after their acute symptoms have subsided and they have improved, but there is paralysis left.

Dr. E. T. Evans: This subject is of a good deal of interest to me. I have seen 55 cases of acute poliomyelitis, and have been called in nearly every case at the University Hospital and there have been 28 cases there.

One point about the use of the serum: Flexner states that if you give horse serum to a monkey it takes about 1/10th as much virus to give it polio as the normal monkey. Autopsies of monkeys so treated show minute hemorrhages; in other words the meningeal barrier is broken down. And for this reason I feel that the use of commercial serum may prove dangerous.

In answer to Dr. Sherwood's question about what to do for these patients after the acute symptoms subside, and there is still paralysis, we have had many such cases and we are routinely keeping the patients at absolute rest in plaster-of-Paris bandages and splints, followed by muscle re-education with muscle support and braces after four or six months.

Dr. E. D. Anderson: It seems to me that in examining a child it is very easy to make a hurried checkup on the arms and legs and it should be done routinely. It is a very simple thing and certainly calls your attention to any impairment of the muscles. The easiest way I have found to do this is to have the child grasp my hand and have him squeeze. Then I have him pull and push against my hand. Then I test for Kernig's with each leg and then have him raise his feet from the bed and then have him push with his feet against my hands. It takes only about a minute and if there are any disturbances you are immediately put on the track of them. I always follow this rule, not only when there is an epidemic but when any child is acutely ill.

Dr. J. C. Michael: In Minneapolis we have had, according to our Health Department, some 42 patients with poliomyelitis during 1930. The first case of the year was reported in the month of July. Eight of those patients were over 19 years of age. These figures show that we have not had very many cases; the number if multiplied by ten would indicate a severe epidemic. I have seen two adult cases, both atypical, during the last three weeks. There is one thing about the pathology of poliomyelitis—the very first lesion in the nervous system is meningeal. The pial and arachnoid vessels are surrounded by increasing numbers of lymphocytic cells. This inflammatory reaction incidentally follows gradually the vessels into the cord or brain stem. Hence one looks usually for pain in the head and back, generalized hypersensitivity, twitching, and drowsiness some days prior to a possible paralysis. The mortality rate is higher in the adult patients.

I think Dr. Platou's paper epitomizes very comprehensively many of the important points in poliomyelitis, especially the use of convalescent serum, which has created considerable interest during the last few years.

Dr. H. B. Clark (St. Cloud): I would like to ask how to obtain and handle the convalescent serum.

Dr. H. B. Hannah: In answer to that question, the State Board of Health has this serum all ready to use, but if you can't get that right away you can take the blood from some adult or other children of the family and separate the serum and use that at once until you can get some of the convalescent serum from the State Board of Health.

In answer to the question as to what to do with the patients afterwards, there is some difference of opinion between the neurologists and the orthopedic men. We do nothing until the pain disappears out of a group of muscles, except to keep the patient absolutely at rest. In perhaps one and a half to two years the end-result can be determined. During the early stages deformity must be prevented by putting on some appliance to prevent stretching of the paralyzed group of muscles. Then it is for the orthopedist to handle the case.

Dr. R. G. Allison gave a lantern slide talk on "Foreign Bodies in the Air Passages."

ABSTRACT OF DR. ALLISON'S PAPER

It has always been comparatively easy to demonstrate foreign bodies that were opaque to the *x*-ray. But is was only a few years ago that Manges, who is associated with Jackson of Philadelphia, described certain definite secondary changes in the lungs that enable us to recognize with a high degree of accuracy nonmetallic foreign bodies in the air passages. There are several things that a non-opaque foreign body can do.

1. It may cause an atelectasis of one or more lobes or even an entire lung with a drawing-over of the heart and mediastinum toward the affected side. In this instance the foreign body is completely occluding the bronchus and allowing air neither to enter nor leave the affected lung.

2. It may not quite completely block the bronchus to the lung or a lobe and give a typical picture of a drowned lung. In this instance, there is no displacement of the heart and mediastinum.

3. By far the most common action of non-opaque foreign bodies is that of a ball-valve action by which air is allowed to enter the affected lung, although the ball-valve action of the foreign body prevents it from leaving. In this instance, it is very necessary to obtain plates at the height of inspiration and at the height of expiration for comparison. In the plate made on inspiration the two lungs look practically alike and the heart and mediastinum are in normal or nearly normal position. In the plate made on expiration, however, the air is not allowed to leave the affected lung. For this reason, we obtain a marked emphysema of the affected lung with a marked displacement of the heart and mediastinum toward the unaffected side. This type of behavior is noted in practically all nuts, fruit pits, and other vegetable materials that may be aspirated into the air passages. These changes can best be shown by lantern slides which I will demonstrate.

Dr. H. M. N. Wynne read a paper entitled "Abnormal Bleeding from the Female Genital Tract." (Published in Journal-Lancet, Feb. 1, 1931.)

Dr. R. T. LaVake, who was scheduled to read a paper on "Everyday Obstetric Problems," asked that his paper be omitted in order to give the Minneapolis men time to make a tour of the new hospital after the meeting.

Dr. F. H. K. Schaaf gave a talk on "The Treatment of Cardiac Diseases" with a plea for the more rational use of the drugs most generally in use at the present time.

Dr. Barron (closing the meeting): On behalf of the Minneapolis Clinical Club, I wish to thank the Staff and Management of the St. Cloud Hospital for the very fine dinner and music we have enjoyed this evening, and for the kind invitation which made it possible to hold this meeting together. And I move that a rising vote of thanks be given them for this hospitality. (Rising vote.)

The meeting adjourned, after which the members were escorted on a tour of the hospital.

The return trip to Minneapolis was made by bus, and the consensus of opinion seemed to be that the evening had been a most enjoyable one.

H. Bright Dornblaser, M.D.,
Secretary.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry:

- Cutter Laboratory
  - Oak Pollen Extract-Cutter; Western Ragweed Pollen Extract-Cutter; Western Water Hemp Pollen Extract-Cutter.
- Gane & Ingram, Inc.
  - Ephedrine Hydrochloride.
  - Ephedrine Sulphate.
- Lederle Laboratories, Inc.
  - Diphtheria Toxoid, ten immunization treatment packages.
  - Diphtheria Toxoid, fifteen immunization treatment packages.
  - Tetanus-Gas Gangrene Antitoxin (Lederle).
  - Gas Gangrene Antitoxin (Polyvalent) Refined and Concentrated without Tetanus Antitoxin (Lederle).
- Mead Johnson & Co.
  - Mead's 10 D Cod Liver Oil with Viosterol.
- National Drug Co.
  - Diphtheria Toxin-Antitoxin Mixture (Diphtheria Prophylactic), one hundred and fifty 1 c.c. vial packages.
  - Diphtheria Toxoid, immunization treatment packages: five (three dose); fifty (three dose); one, five, ten, fifteen, fifty (two dose).
  - Schick Test.
  - Schick Test Control.
  - Tuberculin Old (Human).
- Parke, Davis & Co.
  - Parke, Davis & Co.'s Viosterol in Oil, 250 D.
  - Parke-Davis Cod-Liver Oil with Viosterol, 10 D.
- Winthrop Chemical Co., Inc.
  - Winthrop Viosterol in Oil, 250 D.

A. M. A., October 18, 1930, p. 1179.)

The following articles have been exempted and included with the List of Exempted Medicinal Articles (New and Non-official Remedies, 1930, p. 477):

- E. R. Squibb & Sons
  - Tablets Digitalis Leaves-Squibb 1 Cat Unit (approximately 1½ grains)
  - Tablets Digitalis-Squibb 1 Grain (10 minims U. S. P. tincture)

TRUTH ABOUT MEDICINES

Gas-Gangrene Antitoxin (Combined) Refined and Concentrated-P. D. & Co.—An antitoxic serum prepared from the toxins of *B. perfringens (B. welchii)* and vibrion septique. The quantity of the finished product in the marketed syringes contains 100 units of each antitoxin. It is proposed for therapeutic use against gas-gangrene infection caused by *B. perfringens* and vibrion septique. It is marketed in syringes containing 100 units of perfringens antitoxin and 100 units of vibrion septique antitoxin. Parke, Davis & Co., Detroit.

Inhalant Chloretone, Creosote and Eucalyptol-Sorensen.—It contains chloretone (New and Non-official Remedies, 1930, p. 115) 1.2 Gm. (20 grains); creosote, 2.5 c.c. (40 minims); eucalyptol, 3.75 c.c. (60 minims); alcohol to make 30 c.c. (1 fluid ounce). C. M. Sorensen Co., Inc., Long Island City, N. Y.

Soluble Gelatin Capsules Parke, Davis & Company's Standardized Cod Liver Oil, 10 minims.—Each capsule contains 10 minims of Parke, Davis & Company's Standardized Cod Liver Oil (New and Non-official Remedies, 1930, p. 256). Parke, Davis & Co., Detroit.

Soluble Gelatin Capsules Parke, Davis & Company's Standardized Cod Liver Oil, 20 minims.—Each capsule contains 20 minims of Parke, Davis & Company's Standardized Cod Liver Oil (New and Non-official Remedies, 1930, p. 256). Parke, Davis & Co., Detroit.

Soluble Gelatin Capsules Parke, Davis & Company's Standardized Cod Liver Oil, 2.5 Gm.—Each capsule contains 2.5 Gm. Parke, Davis & Company's Standardized Cod Liver Oil (New and Non-official Remedies, 1930, p. 256). Parke, Davis & Co., Detroit.

Soluble Gelatin Capsules Parke, Davis & Company's Standardized Cod Liver Oil, 5 Gm.—Each capsule contains 5 Gm. of Parke, Davis & Company's Standardized Cod Liver Oil (New and Non-official Remedies, 1930, p. 256). Parke, Davis & Co., Detroit. (Jour. A. M. A., September 6, 1930, p. 729.)

Quinine Bismuth Iodide.—A substance of variable composition containing between 18 and 20.1 per cent of bismuth, between 48.7 and 53.5 per cent iodine; and quinine. Quinine bismuth iodide is proposed as a means of obtaining the systemic effects of bismuth in the treatment of syphilis.

Sodium Potassium Bismuthyl Tartrate.—A basic sodium potassium bismuth tartrate containing from 40.75 to 41.25 per cent of bismuth. It is proposed as a means of obtaining the systemic effects of bismuth in the treatment of syphilis.

Tartro-Quiniobine.—A suspension of quinine bismuth iodide and sodium potassium bismuthyl tartrate in olive oil, each c.c. containing quinine bismuth iodide, 0.072 Gm., sodium potassium bismuthyl tartrate, 0.032 Gm., and camphor, 0.003 Gm. It is proposed as a means of obtaining the systemic effects of bismuth in the treatment of syphilis. It is designed to secure both early action through the presence of water-soluble sodium potassium bismuthyl tartrate, and prolonged action through the insoluble quinine bismuth iodide. It is supplied in 2 c.c. ampules. Spicer & Co., Glendale, Calif. (Jour. A. M. A., September 13, 1930, p. 797.)

Old Tuberculin, Human Strain, Concentrated (New and Non-official Remedies, 1930, p. 360).—This product is also marketed in packages of two vials, one containing a stated amount of tuberculin and the other sufficient diluent to make six dilutions. Eli Lilly & Co., Indianapolis.

Chiniofon-Searle.—A brand of chiniofon-N. N. R. (New and Non-official Remedies, 1930, p. 120). It is also marketed in the form of 0.25 Gm. (4 grains) tablets. G. D. Searle & Co., Inc., Chicago. (Jour. A. M. A., September 20, 1930, p. 865.)

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

EYE, EAR, NOSE AND THROAT

CAUSE AND TREATMENT OF SOME FRONTAL HEADACHES WITH REPORT OF CASES. Dr. Louis Weiss, Newark (Laryngoscope, Vol. XL, No. 12, December, 1930). The author in this paper discusses the history, etiology and treatment of frontal headaches. He reports thirteen cases, along with diagrams illustrating the deformities of the nose causing frontal headaches. He states that in most cases the patients came to his office thinking that they needed a refraction. In practically all of his thirteen cases, however, their refractive error was found to be practically nil, and the headaches were due to some nasal deformity or pathology. He states that nasal obstruction is usually the cause of frontal headaches. As a consequence of these nasal obstructions there may be present a single or multiple sinusitis. Chronic or acute frontal headaches may be due to nasal obstructions alone or in conjunction with sinusitis. Nasal obstructions are usually the primary cause and sinusitis the accompanying or secondary cause.

The proper method of treatment is to remove the nasal obstruction first. The author believes intranasal surgery should be performed as early as possible to prevent nasal deformities; that nasal surgery does not usually mean the obliteration of the nasal contents but a rebuilding of the nasal passages to effect normal breathing; that an objection may be registered to insufficient nasal surgery which leaves the patient with the same symptoms as before.

The paper next deals with the treatment of acute sinusitis.

Thirteen cases of frontal headaches associated with nasal obstruction are reported. It is interesting to note that in all of these thirteen cases reported the patients came in complaining of frontal headaches due to what they thought was a refractive error. The subsequent examination, as illustrated by the diagrams accompanying this paper, revealed that nasal obstruction was the cause of the headaches. The proper surgical treatment in these cases resulted in complete relief of the symptoms.

L. G. C.

CHRONIC SUPPURATIVE OTITIS MEDIA. Gorge E. Shambaugh, M.D., Chicago, Ill. (Arch. of Otolaryng., Volume 12, No. 6, December, 1930). This article has a decidedly conservative flavor; the author stresses the fact that the really difficult problem is to differentiate between those cases which may flare into intracranial complications, and the much larger majority of harmless cases.

This can only be accomplished by the highly trained otologist who gives more emphasis to diagnosis in his practice than to mere operative technic.

For the serious case which may develop intracranial complications no necessary surgery is too radical to be undertaken. These are the cases of course where there is deep caries or cholesteatoma of the temporal bone. A very foul odor to the discharge, after careful cleansing has been carried out, is indicative of caries or cholesteatoma. So also the location of the perforation in the drum membrane is of importance. Central perforations are usually indicative of a less serious infection. Marginal perforations usually denote bony caries. The size of the perforation is of no particular importance. This is true also of the quantity of the discharge. Usually, when the discharge is mucoid in character and not too offensive, the pathology is confined to the lining mucosa only.

Radical operation is undertaken solely to eradicate the dangerous focus of infection and not simply to arrest the discharge, which, in fact, many times continues after the operation. Hearing is frequently decreased or abolished after healing is complete. Every case should have a fair trial with conservative methods. This consists of simple cleanliness. Debris and granulations must be removed from the fundus of the canal. Dry wipe is favored, followed by a boric alcohol treatment and possibly the insufflation of dry boric acid powder. Dry wicks in the canal are not favored by the author, who believes that as much can be accomplished by the above simple method as can by any or all of the myriads of methods suggested.

M. W. W.

GYNECOLOGY AND OBSTETRICS

INTRATHORACIC NEW GROWTHS: Stuart W. Harrington (Surg., Gynec. & Obstet., Nov., 1930, p. 647). The author reviews the results of surgical treatment in twenty-four cases. He believes the recent increase in frequency is due to better methods of diagnosis, namely the roentgen ray, rather than to an actual increase. Sarcoma, malignant lymphoma and endothelioma have yielded to *x*-ray and radium treatment. Adenocarcinoma has not.

Pain, dyspnea and cough were among the chief symptoms. Horner's syndrome was found in three cases. Dyspnea and cough were marked in anterior mediastinal tumors. Vascular changes, not common, were found with tumors of the upper chest and anterior mediastinum.

Of diagnostic methods the general physical examination is of greatest importance. *X*-ray is the most important single method of diagnosis. Preliminary artificial pneumothorax greatly facilitates *x*-ray studies by distinguishing intrapulmonary and extrapulmonary lesions on the one hand and adherence of the lung to an extrinsic lesion on the other. Fluoroscopic examination aids in ruling out expansile aneurysms and substernal goiters which elevate on swallowing. Bronchoscopic examination helps by ruling out primary intrabronchial disease. Injection of the bronchial tree with 40 per cent iodized poppy seed oil is valuable. Exploratory thoracotomy is also resorted to in diagnosis. Pulmonary collapse, one of the associated dangers, is obviated by use of differential air pressure during the operation.

The operative risk is diminished by establishment of preliminary artificial pneumothorax for a few days before operation to allow the patient to become accustomed to unilateral partial collapse and decreased vital capacity. The author says he prefers to operate with intratracheal anesthesia (ethylene and ether) under positive pressure because one never knows when he may accidentally produce a bilateral pneumothorax in these operations. Besides, it is important to fully expand the lung every three to five minutes during the operation in order to ventilate and reestablish circulation. If the tumor is attached to the thoracic wall or springs from the latter, the operative approach is made over the site of the tumor; if the tumor is in the anterior or posterior mediastinum or in the lung, a postero-lateral transpleural thoracotomy is performed. The extrapleural approach is usually unsatisfactory because of the extensive dissection of the pleura off the tumor which is required. Eventual perforation of the pleura with open pneumothorax is very likely. Marked pleural effusion because of the extensive trauma to the pleura is common. Preferably the operation should be done in one stage. The author had only two operative deaths in his series of twenty-four operated cases. The blood pressure is watched closely and saline with glucose given when the blood pressure falls 10 of Hg., and a blood transfusion when it drops 20 to 30.

The most significant immediate complication is dyspnea with cyanosis. Immediate use of the oxygen chamber is frequently a life saving measure. Later complications are pleural effusion and empyema, notably in cases of teratoma. All patients with these complications in the author's series recovered.

Twelve (50 per cent) of the twenty-four cases of the author's series were benign tumors. However, most intrathoracic tumors are potentially malignant. Eleven patients of this series are living five to forty-one months after operation and all are believed to be completely cured.

The most common tumors of the anterior mediastinum are the dermoids and teratomas. These are usually cystic and, of all the benign tumors, most prone to malignant degeneration. Neurofibromata in the author's series were always in the posterior mediastinum.

Histologically the benign tumors in the author's series were neurofibroma, cellular fibroma, teratoma (dermoid), osteochondroma and fibromyxochondroma. The malignant tumors were osteofibrosarcoma, fibromyosarcoma, fibrosarcoma, fibro-osteochondroma, sarcoma, osteogenic sarcoma, malignant endothelioma, adenocarcinoma, and squamous cell epithelioma (dermoid).

Harold J. Dvorak.

MEDICINE

TUBERCULOSIS ABSTRACTS*

The seventh conference of the International Union against Tuberculosis was held in August, 1930, in Oslo, Norway. Representatives from almost every nation attended the meeting. Three main topics were discussed: "BCG Vaccination," led by Professor Calmette of Paris, "Thoracoplasty," opened by Professor P. Bull of Oslo, and "The Teaching of Tuberculosis to Students and Doctors," reported by Professor His of Berlin. Excerpts of the discussions which follow are derived from the Quarterly Bulletin of the Union, Vol. VIII, No. 4.

PREVENTIVE VACCINATION AGAINST TUBERCULOSIS BY MEANS OF BCG

Professor Calmette summarized the status of BCG. He defined immunity as a peculiar state of resistance to reinfections, depending on the presence of a few specific bacilli or a benign, non-progressive tuberculous lesion. Attempts to obtain immunity by killed bacilli have consistently failed. BCG is a strain of living tubercle bacilli, the characteristics of which are hereditarily fixed. When injected into the body, it produces tuberculins and exerts antigenic functions. It has lost

---

*Reprinted from *Tuberculosis Abstracts,* a review for physicians published monthly by the National Tuberculosis Association, March, 1931, Vol. V, No. 3.

all capacity to give rise to progressive tuberculous lesions.

Immunization can take place at any age, provided the individual is free of any bacillary contamination and reacts negatively to tuberculin. Allergic individuals derive no benefit from BCG. Newborn infants of tuberculous families should be inoculated promptly before they have come in touch with virulent bacilli. The culture may be given hypodermically or by mouth. To be successful, vaccination by mouth must occur within ten days following birth, as during this time the intestinal mucosa consists only of protoplasmic cells, and the living elements of BCG are then easily absorbed and scattered in the infant's lymphatic system.

Since 1924, BCG vaccination has been practiced in seven European, and four South American, countries and has been given a trial in many other countries. Vaccination has no harmful influence; the general morbidity and mortality are less among vaccinated children than among unvaccinated, and the tuberculosis death rate among vaccinated children living in tuberculous families is almost nil. Vaccinated infants must, however, be protected for approximately one month after birth, either by isolating the children from the source of infection or by educating those who care for them. Calmette claims that the objections which have been raised against BCG could not be maintained and that the vaccine should be generally applied.

Several delegates reported the results of their experiments with BCG, which deviated but slightly from those of Calmette. Agreement was, however, not unanimous. Among those who disagreed with Calmette are the following:

E. A. Watson of Canada found in his experiments on animals that BCG has not been entirely deprived of virulence. He had also restored virulence to three strains of BCG as the result of inoculation in serial passages. Dr. Kethner of Germany did not admit the proof that BCG is a fixed virus. Professor Lowenstein of Austria thought that vaccination with living bacilli was a delusion. Professor Morelli of Italy attributed the good results obtained through BCG vacciantion to the prophylactic measures which were carried out simultaneously.

THORACOPLASTY IN THE TREATMENT OF TUBERCULOSIS

Professor P. Bull described his personal operative technic and the results obtained by him and his colleagues, on which he bases these conclusions:

Patients with unilateral or practical unilateral pulmonary tuberculosis, in whom an artificial pneumothorax cannot be induced or does not yield the desired results, may be cured by a complete or partial extrapleural thoracoplasty alone or in combination with a pneumothorax or exairesis of the phrenic nerve.

The operation must be undertaken only after consultation with the physician in charge of the case when he has, after a considerable observation period, been able to form a definite opinion on the prognosis of the case.

The other lung must show no clinical signs or, if they exist, they must be slight and stationary.

The extrapleural thoracoplasty is carried out through a paravertebral incision, with resection of the ribs, from the eleventh or tenth to the first, inclusive.

The resection of the ribs must be undertaken as far back as possible, right up to the transverse processes of the vertebræ.

The two-stage operation gives a lower mortality than the one-stage operation.

The operation does not entail any appreciable permanent discomfort.

The choice between a local and a general anesthetic does not seem to affect the results appreciably.

A thoracoplasty is indicated when improvement has not followed three or four months' sanatorium treatment, and an artificial pneumothorax cannot be induced with success.

Recurrent hemoptyses constitute an additional indication for operation.

Cavities as large as, or larger than, a walnut heal more rapidly and surely after an operation than under expectant treatment.

If a cavity does not collapse completely after a thoracoplasty, it may be made to do so by a pneumolysis and the employment of a fat graft or a paraffin filling, plugging with tampons, or even drainage.

The chronic productive forms of pulmonary tuberculosis are those best suited for a thoracoplasty. It is most dangerous to touch the purely exudative forms.

From 35 to 45 per cent of the patients who cannot be saved by other means may be so by a thoracoplasty, becoming to all intents and purposes fully fit for work.

Some 20 per cent benefit from the operation, but ultimately die of tuberculosis.

Some 6 per cent become worse after the operation.

Some 10 per cent die from operation; *i.e.,* within eight weeks of it.

All sanatorium physicians and general practitioners should know the indications for, and the results of, extrapleural thoracoplasties. No one has any longer the right to withhold from patients suitable for this operation the chances it gives them.

THE TEACHING OF TUBERCULOSIS TO STUDENTS AND DOCTORS

Professor His had questioned all civilized countries relative to the teaching of tuberculosis. Replies to this inquiry constitute the basis of the report and justify the following conclusions:

The teaching of tuberculosis must be given within the compass of the clinical teaching of internal medicine, children's diseases, surgery and dermatology.

These clinics must consequently admit a certain number of tuberculous patients in all stages of the disease and maintain, if necessary, a connection with tuberculosis departments in other hospitals, sanatoria, and dispensaries. Students must be given an opportunity to visit sanatoria and dispensaries.

Special courses and opportunities for practical work on tuberculosis should be made available, but they need not be compulsory.

Postgraduate courses for doctors on the pathology, diagnosis, treatment and prophylaxis of tuberculosis must be organized in such a way that every practitioner may get an opportunity, at certain intervals, to bring his knowledge up to date.

Moreover, it is highly desirable that complete courses be organized on tuberculosis as a whole, or on certain specified problems.

A doctor who wishes to improve his knowledge of this subject ought to be given an opportunity to make a practical study visit to a sanatorium or a dispensary.

Medical officers need a thorough training and postgraduate knowledge in this field of medicine.

Attendance at national and international conferences ought to be encouraged by public authorities.

Dr. Willard B. Soper of the United States, one of those who took part in the discussion, remarked that "instruction in the different medical schools shows great differences, which can almost always be ascribed to the presence or absence of one or more individuals on the teaching staff who are vitally interested in this disease, men with whom the study of tuberculosis has become a passion and who find their greatest satisfaction not only in adding to their sum of knowledge but also in imparting it to others."

He described the postgraduate course given at the Trudeau School of Tuberculosis at Saranac Lake, which he regarded as a great influence in raising the standard of knowledge of tuberculosis in America.

PEDIATRICS

FEEDING CONVALESCENT CASES OF COLITIS: Mather Marvin McCord, M.D., Rome, Georgia (Arch. of Ped., Vol. XLVII, No. 11, November, 1930). The lack of proper refrigeration for the care of liquid milk causes much of the summer bowel trouble with infants.

More babies die from starvation during convalescence than during the acute stage of colitis.

Dried milk of the 12 per cent variety furnishes just enough of digestible fats to aid in making a normal soap stool in the child's bowel without throwing a burden on it by feeding milk too high in fats. When the soap stool is formed the food acts as an astringent in the bowel. When this action takes place there is no need for drug astringents.

Dried milk is safer, more easily digested, and more dependable than liquid milk in hot weather. If properly used it will hasten recovery following attacks of colitis.

R. N. Andrews, M.D.

ALIMENTARY ANEMIA: Wm. Willis Anderson, M.D., Atlanta, Georgia (Arch. of Ped., November, 1903, Vol. XLVII, No. 11). Alimentary anemia as an entity was first described by Czerny in 1912. Kleinschmidt, in 1916, gave a more detailed report of this condition.

The majority of cases of alimentary anemia occur between the ages of three months and two and a half years. Not only is the spleen enlarged in many cases, but the tonsils are also hyperplastic.

Most of the children with alimentary anemia give a history of having existed almost altogether on a milk diet, whether it be breast milk or cow's milk. Large quantities of milk not only fail to benefit this type of anemia, but, taken without a balanced ration, will cause the anemia to become more severe.

Alimentary anemia may be divided into two groups: one group of children showing malnutrition, while the other group appears plump and are hearty eaters. These children may be of average weight or even a little overweight. In both groups the blood findings are identical. There is, more or less, a marked reduction of the hemoglobin. The red cells may be reduced in number or be of an average count. The white cells are usually slightly increased.

As a rule, if the hemoglobin is below 50 per cent it is wise to give human blood, preferably by transfusions. The amount of milk is reduced to a pint or a pint and a half a day, and a more liberal diet prescribed. Iron in some form is usually efficacious, whether it is simple reduced iron, syrup iodide of iron, or ferri carbonas saccharatus.

Although the author believes there is a definite type of anemia which is largely concerned with diet, hygiene, a reserve store of iron in the liver and general bodily development, he feels there are numrous phases in the condition as yet unexplained.

R. N. Andrews, M.D.

DIPHTHERIA OF THE UMBILICUS: J. S. Montgomery, M.D., Detroit (Amer. Jour. of Dis. of Children, Nov., 1930, Vol. 40, No. 5). Diphtheria of the umbilicus is a disease that is seldom recognized clinically. These cases could be divided into three classes: (1) those showing no clinical evidence of infection, but only positive cultures from a somewhat moist umbilicus, (2) those showing only a slight caseous deposit with positive cultures, and (3) those with more extensive evidence of infection.

Comby points out that diphtheritic infection of the umbilicus does not differ greatly from non-specific infections of the same region, and urges that bacteriologic examination be resorted to more frequently. He also points out that the disease is rarely febrile, and that the infant may continue to nurse and to gain weight, the majority of these patients having gained weight while in the hospital.

R. N. Andrews, M.D.

ACUTE HEMOLYTIC ANEMIA IN CHILDHOOD: Sylvan D. Lazarus, M.D., Brooklyn (Amer. Jour. Dis. of Children, Nov., 1930, Vol. 40, No. 5). In 1925, Lederer first called attention to a form of acute, rapidly progressive anemia, accompanied by fever, general weakness, marked pallor and splenic and hepatic enlargement, with severe leukocytosis and erythroblastemia. Another striking characteristic of the picture was the rapid, permanent recovery to normal, following a transfusion of whole blood. The recovery not only demonstrated itself clinically by the general improvement of the patient, but also in the return of a normal hematologic picture.

In reviewing the literature of pediatrics, one finds no direct reference to this entity, although these cases are probably seen and described as acute atypical anemias. Clinically, the picture is so alarming, rapid and severe, that it indelibly impresses one, and the dyspneic breathing and air hunger especially simulate the picture of severe poisoning.

The marked progressive anemia, the general tenderness of the body, the fever, the increased pulse and respiration rates, the suggestive abdominal symptoms, such as vomiting and the tenderness of the abdomen accompanied by splenic and hepatic enlargement, are the cardinal symptoms. The initial blood picture before transfusion is suggestive of severe leukanemia.

The most striking feature of this entire condition is the rapid recovery, judged by clinical symptoms and improvement of the blood picture, following transfusion of whole blood. All the cellular elements of the blood rapidly assumed a normal picture and the abnormal elements, such as nucleated red cells and megaloblasts, disappeared. No icterus was noted in these cases.

Etiologically, nothing has been found as a specific cause, although an infectious origin has been suggested by some authors. Subsequent infections do not cause a return of the syndrome.

R. N. Andrews, M.D.

SURGERY

UBER DIE RESULTATE DER OPERATIVEN BEHANDLUNG DER GRAWITZTUMOREN. E. Ljunggren (Zeitschrift fur Urologie, 1930, 24:883-894). A report of fifty-eight epithelial neoplasms of the kidney, three of which are classified as adenomata. All were treated by nephrectomy. There were six operative deaths (10.3 per cent).

The author calls attention to several important questions in determining the suitability of a case for operation. For example, nephrectomy was done in two cases with demonstrable pulmonary metastases. The first was symptom-free and gained weight for twelve months, but died twenty months after operation. The second was symptom-free four years after operation, the pulmonary lesions having remained stationary. He refers to the case of Bumpus, whose patient was living and well, his pulmonary metastases having disappeared two and one-half years after operation.

Thirty-nine of the fifty-eight cases had a thrombus of tumor tissue in the renal vein as verified by microscopic examination. Six died from operation. Twenty-six per cent were well five years or more after operation. In four cases it was known that tumor tissue was left in the vein. One of these died of other causes five years and eleven months later, and at autopsy no trace of tumor tissue could be found. The author feels that spontaneous necrosis of the remaining fragment must have occurred and cites the literature to the effect that this is not so uncommon as might be supposed.

Of the fifty-two patients who survived operation, twenty-five died with recurrence, six of these surviving for from five to eleven years, four died of other causes, ten months to thirteen years after operation, while twenty-one were free from recurrence from one to ten years, fourteen being alive more than six and ten more than ten years. Counting the patient who lived thirteen years and died of other causes, there were 19 per cent of ten year cures, while 45.8 per cent of the cases operated upon ten or more years ago survived the ten year period.

The author points out that it is unsafe to speak of cures of shorter duration than ten years, since the literature contained many instances of death from recurrence after that interval.

The paper represents a careful study of the end-results of operation for "hypernephroma" and makes it clear that operation is not contraindicated by the presence of pulmonary metastases, nor the prognosis made completely hopeless by invasion of the renal vein. The number of ten year cures is remarkably high and most encouraging.

Donald C. Creevy, M.D.

MIXED TUMORS OF THE KIDNEY IN INFANCY AND CHILDHOOD. H. L. Kretschmer and W. G. Hibbs (Surg., Gynec. & Obstet., January, 1931, Vol. 52, pp. 1-24). The authors report seventeen cases of malignant tumors of the kidney occurring in infants and children. The study brought out the interesting fact that in many instances the true nature of the tumor was not recognized either at the time of operation or at the time histological examination was made. Theories of pathogenesis are discussed.

The involved kidney is globular to oval in shape, solid, opaque, subdivided into lobules and somewhere on the surface a nodule of kidney tissue usually remains. In this series the kidneys weighed from 235 to 1,530 grams. Microscopically there is myxomatous tissue in which gland or duct-like figures are imbedded. Striated and unstriated muscle fibers are other elements seen. Necrosis of the tumor is often marked. Extension and metastasis of these tumors is exceptional unless the original tumor is large.

Clinical features reported are as follows: Sex, 14 males, 3 females; age, 3 months to 6.5 years; side involved, left 10, right 5, bilateral 2. Palpable tumor was the predominating symptom. Fever occurred in nine patients; pain in the abdomen in six. Only one had urinary frequency. Gross blood in the urine is rarely present. In every case there was a secondary anemia.

The authors emphasize the need of cystoscopic and pyelogram studies in making a diagnosis. Prognosis is bad, as sixteen of the seventeen patients died. Case reports reveal that both surgery and deep *x*-ray therapy were employed in the treatmnt of these patients, but the authors do not make any recommendations regarding treatment.

Herbert A. Carlson, M.D.

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

Microbiology and Elementary Pathology. Charles G. Sinclair, B.S., M.D. 362 pages. Illus. Price $2.50. Philadelphia: F. A. Davis Company, 1931.

Practical Treatise on Diseases of the Digestive System (Vols. I and II). L. Winfield Kohn, M.D., F.A.C.P. 1125 pages. Illus. Price 2 Volumes, $12.00. Philadelphia: F. A. Davis Company, 1930.

The Measurement of Man. J. A. Harris, C. M. Jackson, D. G. Paterson, R. E. Scammon. 215 pages. Illus. Minneapolis: University of Minnesota Press, 1930.

Physical Diagnosis. Warren P. Elmer, B.S., M.D., and W. D. Rose, M.D. 903 pages. Illus. Price, $10.00. Saint Louis: The C. V. Mosby Company, 1930.

A Manual of Normal Physical Signs (Second Edition). Wyndham B. Blanton, B.A., M.A., M.D. 246 pages. Illus. Price, $3.00. Saint Louis. The C. V. Mosby Company, 1930.

Medical Jurisprudence (A Statement of the Law of Forensic Medicine). Elmer D. Brothers, B.S., LL.B. 309 pages. Price, $3.50. Saint Louis: The C. V. Mosby Company, 1930.

Intestinal Toxemia (Autointoxication) Biologically Considered. Anthony Bassler, M.D., F.A.C.P. 433 pages. Illus. Philadelphia: F. A. Davis Company, 1930.

Proceedings of the Twenty-fourth Annual Convention of the Association of Life Insurance Presidents. 280 pages. Illus. 1930.

Certified Milk Conferences Held in 1930. Proceedings of A. A. M. M. C., C. M. P. A. A. and M. C. M. P. 354 pages. Illus. Detroit: Certified Milk Producers' Association of America, 1930.

NERVOUS INDIGESTION—Walter C. Alvarez, M.D., Associate Professor of Medicine, University of Minnesota (The Mayo Foundation). 297 pages. Price, $3.75. New York: Paul B. Hoeber, Inc., 1930.

In this beautifully written and entertaining little book, we have a discussion of that most common and most neglected of disorders, so-called nervous indigestion.

As we grow older, we almost all appreciate the fact that patients of the "nervous" type do not lend themselves to teaching purposes, so we see little of them in school. The pictures they present are not definite and even if they are presented to us, we disregard them in favor of the definite pathology of ulcer, gall stones and the others. But whether we admit it or not, we all treat patients with functional disorders with more or less functional methods.

"Nervous Indigestion" is, however, not simply a serious discussion of this most important theme, but its sidelights on human nature are so amusing that one is loath to put the book aside until it has been completely read.

H. B. Sweetser, Jr., M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

FOR SALE—Because of illness a small hospital and practice are for sale at great reduction in town of 800 inhabitants, prosperous community, German or Scandinavian physician preferred. Half cash, balance terms. Address D-121, care Minnesota Medicine.

FOR SALE—Instruments and office equipment of the late Dr. A. E. Comstock. See or address Dr. C. F. McNevin, 714 Lowry Building, Saint Paul, Minnesota.

FOR SALE—1 Standard Type "D" X-Ray apparatus 100 P.V.K. with auto-transformer and Rheostat control. Perfect condition. Also new Coolidge tube. Address D-123, care Minnesota Medicine.

WANTED—Capable man licensed in Minnesota to take charge of established eye, ear, nose, and throat practice. Must be able to do refractions. Address D-122, care Minnesota Medicine.

GOOD OPENING—For physician in Northome, Minnesota. Surrounding country is good and covers a big territory. Address H. Brunelle, Northome, Minnesota.

PHYSICIAN'S OFFICE FOR RENT—Best location Midway district, corner Thomas and Hamline, Saint Paul. Rent $25.00 a month. Inquire at dentist's office.

AORTIC STENOSIS WITH CALCAREOUS NODULES IN THE AORTIC VALVES*

E. L. Tuohy, B.A., M.D., F.A.C.P., and P. F. Eckman, B.A., M.D.
Duluth

Sir Dominic John Corrigan[1] first directed interpretation of aortic disease along an intelligent correlation of etiology, pathological sequences and physiological effects. Few great medical scientists have ever had as much acclaim in their own lifetime or retained it so well in the century which has followed.

From the standpoint of etiology it is illuminating to observe that medical science gained little actual working knowledge of syphilitic aortic disease passing from the period before to that after Schaudinn.[2] Dark field studies gave early diagnostic criteria of syphilis, but nothing new pertaining to mesaortitis or separated aortic valve cusps. In a decade when the other great agency inducing aortic disease—rheumatic fever—is discussed by such a host of the world's acute bacteriologists, and with such varying discordant impressions, it may hearten us to speculate that discovery of a specific agent causing rheumatic fever and its congenera† may give us more scientific than practical satisfaction.

Following the Virchow epoch, the heart and aorta came into the most exacting evaluation of anatomical form and pathological imprint. The roentgenology of today (after Kreusfuchs, Assman and others) has given us the most direct and accurate clinical confirmation in the living for what had previously been so dogmatically outlined by Continental necropsists. Outlines have come into their own, and the clinician's consciousness comes to be more aroused by his eyes than by his ears. Lest, however, we be unfair to Harvey and Laennec, let us hasten to add that English and Dutch clinicians and physiologists (Mackenzie 1853-1925, Einthoven 1860-1927, Lewis 1881- , and their school) with consummate disregard for Teutonic mensuration of diameters and weights, introduced a flood of information about how hearts worked and aortas withstood, rather than how they looked on pathological specimen trays. There still remains the constant need for a harmonizing of the data accruing from the various methods of approach; none up to date has yielded all the information or all the facts. The American Heart Society well exposes our present dilemma in urging clinicians to utilize an involved technical schema of diagnosis and classification—etiological, anatomical and physiological. The end is not yet: the stage is now set for biochemical and biophysical investigations bearing upon general metabolism; the cardiologist concentrates for the moment upon entities as disastrous as angina pectoris or far reaching as calcium deposition in blood vessel walls. In both there is a fundamental oxygen and nutrient deficiency, and seemingly a chance emplacement determines whether the resultant death shall be immediately of the body as a whole or gradually through loss of dispensable parts. The prolongation of life expectancy is focusing attention upon factors (metabolic, endocrine, hereditary or unknown) other than the well known rheumatic infections and syphilis. Degenerative lesions attributable to senility defy arbitrary rulings as to age: the young man of thirty-eight dies of coronary infarction with only one centimeter of the descending branch of his left coronary involved; the man of eighty-five lives with his aorta and cerebral vessels laid down as if in concrete. In a country or historical period when the average life tenure was twenty to twenty-five (England in Queen Elizabeth's time: portions of India today) aortic diseases would be largely rheumatic and rarely congenital. A period where the tenure stepped up to thirty-six or forty (the United States at the time of the Civil War) would include in addition many syphilitics, with a heavy incidence among the colored race. The conditions of today, with a life expectancy around fifty-eight to sixty, find many living into the eighth decade, and a busy practitioner is confronted with a major problem of aortic disease and heart failure in hypertensives and arteriosclerotics, where neither rheumatic fever nor syphilis registers high in etiological or statistical columns. The term "cardiovascular disease" is too all-inclusive. Life insurance mortality tables indicate the need for intimate analyses of important subdivisions within this universal conglomerate.

---

*From the Medical Department of the Duluth Clinic, Duluth, Minn.

†The group of what M. J. Rosenau calls "the whole rubric of the septicemias."

Unanimity in the opinion of observers has come in the matter of the lack of causal connection between primary or essential hypertension and syphilis. We know that "arteriosclerosis is only encouraged or somewhat hastened by essential hypertension." Very high grades of atherosclerosis (the senescent type) occur without hypertension. Out of the 70 to 75 per cent of essential hypertensives dying of heart failure fully one-third have coronary disease. Of the coronary group not more than one-third have typical Heberden's anginal attacks. In addition, an increasing number of well authenticated and supported cases are coming to light with typical angina, where the caliber of the coronaries is essentially undisturbed: the extra heart effort in hyperthyroidism and the anoxemia of high grade Addisonian anemia.‡ We propose to add another instance associated with rigid, calcareous nodules, incapacitated aortic cusps, with aortic stenosis. Gradually it is becoming apparent that Allbutt was thinking squarely when he refused to divorce his attention from the aorta and its sigmoid portion in anginal states. The debate over whether coronary or aortic states product angina pectoris is yielding to the certainty of opinion that both can and do produce it. Keefer and Resnik[3] not only reiterated Heberden's dictum that true angina pectoris was a lethal malady, but they directed attention at the same time to the probable reason for sudden death in aortic disease, and to the role played by anoxemia of the heart muscle in anginal attacks. Those who have followed a goodly number of aortic insufficiency cases need not be told of this tendency to sudden death. The anoxemic heart muscle theory, with ventricular fibrillation as the final chapter, backed up by poor diastolic pressure in the aorta, is now much stressed by commentators.

At to the features involved in the antemortem diagnosis of aortic stenosis, further preliminary comment is not amiss. The aversion to the making of a clinical diagnosis of aortic stenosis is an inheritance from overzealous student days, when every basal systolic murmur meant aortic stenosis. Without decrying the art of Auenbrugger (1722-1809)[4] or the thoroughness and foresight of Corvisart (1755-1821)† and the possibilities of percussion in general, it is fair to state that it requires less skill to show up accurate heart outlines teleoroentgenographically than to judge the same without roentgen aid. These better outlines have done much to clarify the diagnosis of single and multiple valve defects where *inspection* can the better augment and safeguard auscultation. It must be granted that rough, sclerotic valves in the aged, and factors of heart rate, thin chest wall, and many others, in the young, produce rough systolic murmurs at the base; but these hearts, independent of hypertension, heart fixation or kidney disease, are not enlarged. In true rheumatic endocarditis isolated aortic involvement must be very rare. Where rheumatic aortic insufficiency is present with stenosis the former is the dominant lesion as expressed physiologically (pulsus celer, widespread flopping mercury level in sphygmomanometer—all signs of extended pulse pressure) and decides the pattern of the heart outline. Independent of syphilis, and likely independent of rheumatic fever, a third agency makes the aortic cusps so rigid and unyielding as to produce the most extreme grades of stenosis.* It does so extremely gradually, and without either signs of heart infection or early congestive failure. Insufficiency of minor grades invariably accompanies it, but it is always in the background and is entirely secondary to the dominant lesion, which is stenosis. This lesion is coming to be known under the name "calcareous nodules" in the aortic valves. The name of Mönckeberg[5]† is often linked up with discussion of calcareous changes in the blood vessels of the extremities, and with a discussion of the pathology of the aortic valves.

---

‡The list is constantly growing: a miscellaneous group now includes paroxysmal tachycardia, anemia with myxedema, arteriovenous aneurysm and others.

†Corvisart, Jean Nicholas. Auenbrugger wrote his thesis upon percussion probably about 1751. Corvisart (physician to Napoleon and Josephine) popularized this epoch-making diagnostic agency, and has gained much in the appreciation of posterity by refusing to credit himself with its rediscovery.

*Pulsus tardus and characteristic polygraphic tracings are not mentioned here. The finding is only confirmatory and the method is becoming obsolete.

Clawson, Bell and Hartzell[6] have very well described the condition which we are reporting. Although their article confines itself to a discussion of the pathological changes found in old valvular defects and has no mention of associated clinical features, those interested should carefully read their description. At a clinic given later by one of the authors (Clawson) he appealed to the clinician to look for these lesions antemortem. This appeal, together with the fact that we have found several such hearts at our regular clinicopathological conference at St. Mary's hospital, caused this possibility to gradually filter through our clinical consciousness, and induced us to venture such a premortem diagnosis. The diagnosis has now been made six times; in three cases we have had autopsy confirmation. In retrospect, we have likely overlooked not a few of these same types. The first impression of well trained internists on introduction to the subject is to classify this lesion as a museum curiosity; to spend an hour equivocating about the cause—grouping it on the one hand as simply an evidence of "an old healed rheumatic valvulitis," or as the result of systemic arteriosclerosis, with special selection of the aortic cusps. Finally, a few deny the clinical existence of the entity because, forsooth, "we have enough etiological and diagnostic confusion without introducing it!" Until something more definite is known concerning the physiochemical conditions behind tissue infiltration with calcium, the manner of "calcareous nodule" deposits in aortic valves is of infinitely less clinical moment than the fact that such a state can silently produce very large hearts, with thick, dilated left ventricles; that the process may begin much earlier than the usual atheromatous sequence develops universally; that it is often seen most typically in those beyond the age where those with multiple rheumatic valve defects are likely to reach; that associated with the syndrome there are no inflammatory reactions evident either in vivo or in the aortic leaflets when examined postmortem; that it can produce a situation at the base of the aorta yielding typical angina, without the characteristic narrowing along the course of the coronaries.

The following case summary is submitted in some detail because it well illustrates these features.

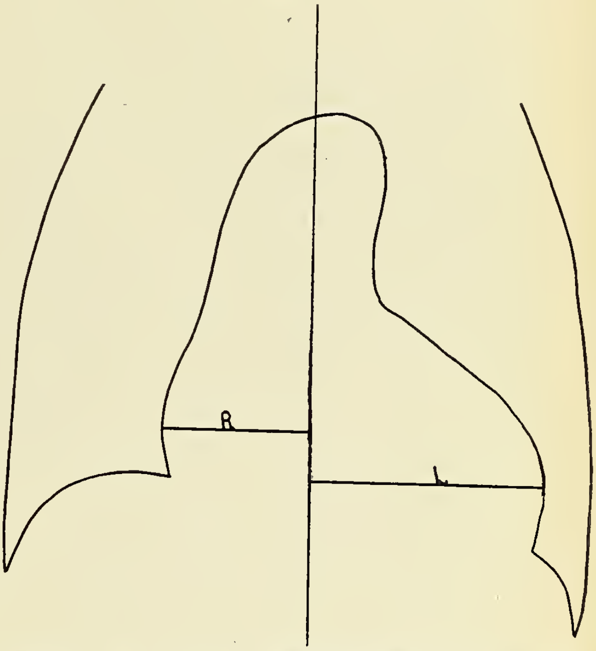

Fig. 1. Case 1. W. H. Teleoroentographic tracing made in December, 1929. Original measurements: right, 7 cm.; left 10 cm.

CASE SUMMARY

Case 1.—W. H., a male, married, aged 37, was first seen February 23, 1919.

Nothing bearing upon later developments came through an analysis of his own family history. His wife had contracted syphilis from her first husband. This knowledge only obscured the issue as to his illness. Three sisters and one brother were living and well.

When young he had had scarlet fever.

In 1913 he had been ill with typhoid fever for about five weeks, but seemed to fully recover. Ten years previously he had had some indigestion, with a marked tendency to "water brash about one hour after eating." There was no suggestion of a rheumatic history or its equivalent.

---

†We have perused his two original articles in Virchow's Archives for Pathological Anatomy and Physiology (the first in 1903, VIII, 171, p. 141, the second in 1904, CLXXVI, 472) with great interest. Mönckeberg's name is most familiar to pathologists in terms of his first article, which emphasized the frequency of media calcification in the extremities in contrast to the intimal changes in important central arteries, chiefly the aorta, the coronaries, and arteries at base of brain. He contends that the processes involved may occur synchronously, but as a rule are distinct and different tendencies. In the second article Mönckeberg stresses the importance of the media in the matter of the calcification of the aortic cusps. He analyzed fully the histological layers comprising the valve cusps, and found a difference between the ventricular surface below and the aortic above, in the latter a preponderance of media-like tissue, with horizontally arranged connective tissue, constituting the main part of the valve and containing few elastic fibers. He states that most people after thirty-five seem to have a thickening of the proximal edge of the aortic valve, leading gradually to palpable and visible yellowish-white areas. The important point is that these begin in the media-like layers. The process continues through fatty degeneration, focal necrosis and chalk deposits, with confluence and distortion. He states that the process may go ultimately to the outer margin of the valve. After the calcareous deposits occur he states that they may cause a deposit of fibrin, which further accentuates the condition and leads to functional valve interference. While the early development obtains only in the aortic component of the valve, later, of course, the other two layers may be distorted, and, as has been stated, these masses can be felt projecting through toward the ventricular side. He finds no relationship between arteriosclerosis, beginning in the aorta, and these lime deposits.

Briefly stated, his immediate complaint was that of indigestion: a discomfort from one to one and one-half hours after meals.

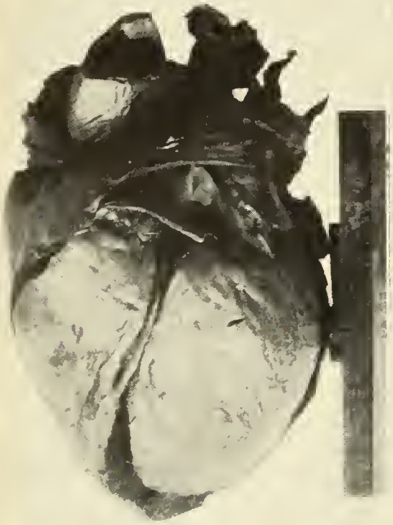

Fig. 2. Case 1. Front view of sectioned heart (1,050 grm. wgt.). Centimeter rule at side.

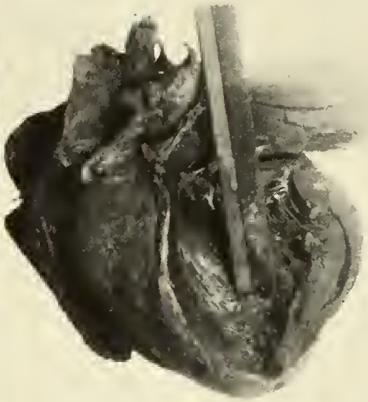

Fig. 3. Case 1. Showing thickness of left ventricular wall.

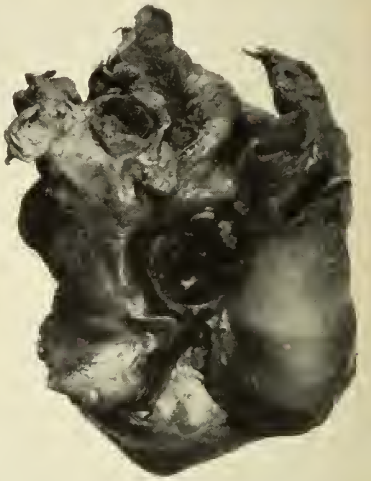

Fig. 4. Case 1. Same heart viewed from above. Aortic cusps too dark to show detail.

The essential findings after a thoroughgoing examination, including roentgen studies of the gastrointestinal tract, were quite negative except for relatively high gastric acids.

He responded very well to the exhibition of alkalies and frequent feedings.

The features pertaining to the findings of his chest examination were of the greatest significance in the terms of succeeding events: There was a rough systolic murmur, heard best at the base and transmitted up into the neck vessels, with a fairly definite diastolic murmur heard just to the left of the sternum in the third interspace. The systolic murmur was widely distributed and could be heard also to some degree in the back.

Several Wassermanns of the blood were taken, and all were negative. In fact, he had a short period of anti-specific treatment based upon the above history of his wife, and the general supposition was that as an aortic diastolic murmur was present and we could not prove that he had had rheumatism, he probably had had syphilis!

Finally, when seen two months later, he was much improved, and he was catalogued as an instance of rheumatic valvular heart disease, with aortic insufficiency and some degree of aortic stenosis. The heart was then only slightly enlarged, the left ventricle showing the major degree thereof.

He reported later that he worked regularly. He had occasional winter colds, but no unusual cough, dyspnea or difficulty until in December, 1928. Although he had to walk only a matter of three blocks, whenever he did so in colder weather or against heavy wind, he experienced pain across the chest, substernal, radiating out toward the left arm. This would disappear if he stopped to rest, but if he persisted it would become a grinding, boring, torturing distress. These attacks occurred only on effort.

Examination at that time showed a regular heart, with a pulse rate of 80. The patient had an excellent appearance; no cyanosis. However, examination over his precordium yielded evidence of a very large heart, with a strong systolic thrill felt over the upper chest, and corresponding with this a very loud, rough murmur heard over the entire chest, and very audible in the back. There was in addition a short diastolic murmur heard at the second aortic space to the right and the third interspace to the left of the sternum. There was, however, no drop in the diastolic pressure; the systolic pressure about 150. The heart outline was globular (Fig. 1). The electro-cardiographic evidence was essentially negative except for inversion of the T-wave in Lead I, a ventricular predominance, and some slight evidence of "arborization defect" or block. It was then obvious that we were dealing (and had been from the beginning) with a very high grade aortic stenosis, with a minimum degree of aortic insufficiency. We had in the meantime been "tuned in" to the possibilities of another etiology. Treatment had no effect in reducing his anginal attacks, but they were never severe except under the influence of effort. Up to March 30, 1930, he had no marked evidence of visceral congestion. However, he soon developed extreme dyspnea, and died characteristically of slowly progressive myocardial exhaustion.

The pre-autopsy diagnosis was "calcareous nodules in the aortic valves, with aortic stenosis, cardiac hypertrophy, chronic visceral congestion with edema." At autopsy the heart was found to weigh 1,050 grams, with extreme hypertrophy and dilatation and thickening of the left ventricular wall. There was a high grade of stenosis of the aortic valves, with a slitlike opening in the middle, yielding a limited degree of aortic insufficiency. There was confirmation of the visceral congestion as calculated. The mitral valves were somewhat thickened but functionally undisturbed. The aortic valve showed extensive calcification, appearing chiefly on the upper surface, but could be felt from underneath. The edges of the valves were densely adherent to each other except a central portion forming an irregular triangular opening, slitlike in character, with rigid edges. When measured, the wall of the left ventricle was 2 cm. in thickness, and that of the right 0.5 cm. (Figs. 2, 3 and 4). The root of the aorta itself showed only moderate yellowish athermatous plaques, and the openings of the coronary ostia were not disturbed. The coronary vessels appeared to be somewhat wider than normal at their openings, and, while showing a few yellowish plaques here and there, were thoroughly patent throughout their larger branches. The myocardium, aside from its increase in bulk, seemed little changed.

COMMENT

Clawson, Bell and Hartzell reported fifteen such cases out of a total of 280 cases of nonsyphilitic valvular heart disease studied. Touching only upon the main incidents in their description, this case is in general conformity with theirs:

1. Marked thickening and stiffening of the aortic valve leaflets due to calcareous nodules within them.
2. The portions of the leaflets between the nodules are of normal thickness and do not show inflammatory hyperplasia.
3. Union and adherence of the edges of the valve leaflets (the most definite feature involved, indicating the possibility of an inflammatory adjunct in the causation).
4. The nodules project and appear on the aortic surface, but are easily felt from the ventricular surface (Fig. 5).
5. The aorta itself, except for about 1 cm. up from the edge of the valve bases, is singularly undisturbed. (Older clinicians maintained that aortic stenosis shields the aorta from systolic shock; hence conversely the tendency to aortic atheroma in young athletes.)
6. The nodular lesions are singularly unlike ordinary intimal atheroma commonly seen within the endocardium and intima of the aorta.
7. Consulting the original article of Mönckeberg it will be seen that this calcification process is one of media degeneration and invasion. The etiological and determinative factors are, as yet, speculative. It is different from and independent of ordinary (intimal) atherosclerosis.
8. If death does not supervene from other causes the process can result in extreme degrees of aortic stenosis with enormous hearts.

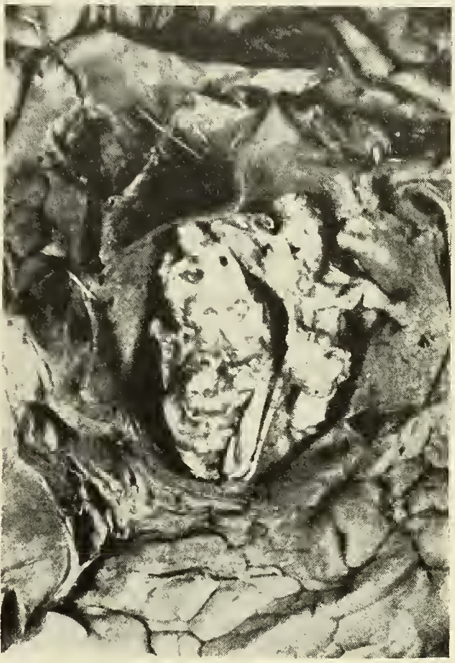

Fig. 5. Cut taken from reprint of article by Clawson, Bell and Hartzell, because it shows so clearly the confluent calcareous nodules in one of their cases. (Amer. Jour. Path., Vol. II, Plate 40, No. 30. Valvular Diseases of the Heart.)

Case 2.—Since the heart found in this forty-nine-year-old man has been found exactly copied in two other autopsies, all descriptive and analytical detail will be much condensed.

J. H. G., a male, aged 44, was observed between the dates November 29, 1924, and his death, November 26, 1927.

At autopsy he had a 1,100 gram heart, globular in shape, and with colossal left ventricle thickening. The same extreme degree of aortic stenosis was seen, with only a slitlike fissure in the center. Curiously, many attendants who saw him fell upon his obvious "diastolic aortic murmur," and were loath to abandon the possibility (at his age) of syphilis, despite his negative history and many negative Wassermanns.

His blood pressure received a good deal of attention, especially in view of the fact that the diastolic pressure never dropped below 100; the systolic advanced near his demise to about 200. His "precapillary arteries" studied postmortem were not those of primary hypertension.

Clinically, it was the general impression that he had "rheumatic endocarditis with aortic insufficiency and stenosis." Suffice it to say that the autopsy showed some fibrotic areas in the myocardium (he died with increasing cardiac dyspnea and visceral congestion), his aortic intima was smooth, soft, and free of atheroma. There were a few yellowish spots seen on the wall of the traced out coronaries, but their patency was not disturbed. The other valves of the heart were normal.

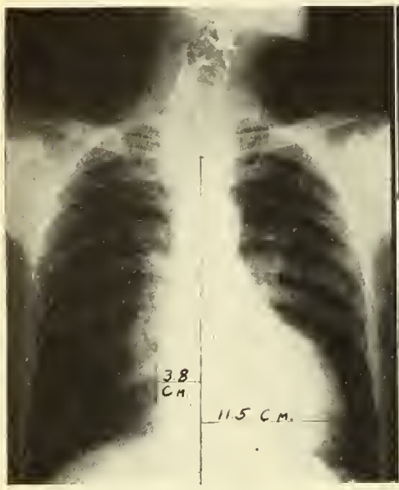

Fig. 6. Case 4. J. V. Chest film, six feet.

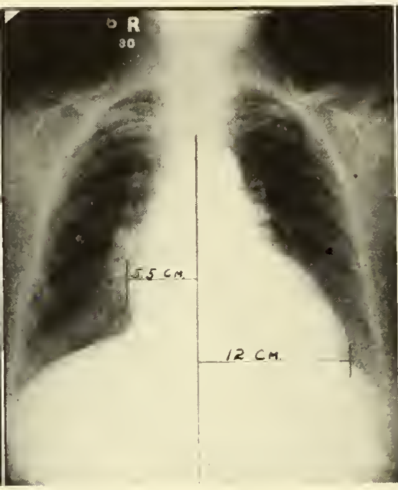

Fig. 7. Case, Mrs. P. W. Six feet, X-ray chest film.

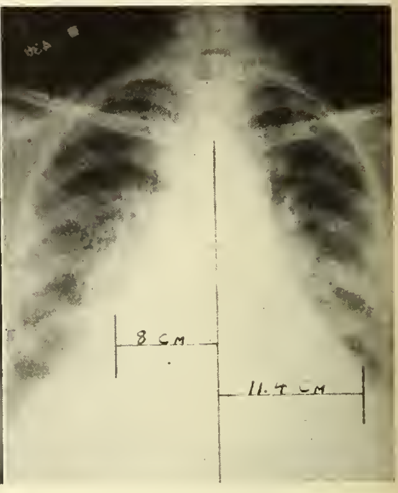

Fig. 8. Case 6. Mrs. A. H. Measurements distorted since film was taken at bedside, short focal distance, and hilus shows abundant evidence of venous congestion.

Case 3.—In contrast to these two men, Mrs. L. St. M., aged 63, came to autopsy with the same type of heart, weighing 650 grams (heavy, indeed, for a woman).

Little is known about her clinical story except that she had had "heart trouble for twenty years." There had been a number of decompensations, and death supervened, with copious spitting of blood, and there were numerous hemorrhagic infarcts.

Here, also, the process was confined entirely to the aortic valves.

We have three other patients under observation upon whom we have made the diagnosis of such aortic valves. It is self-evident that the diagnoses can as yet be largely "impressions," but we feel that with the definite globular heart, with decided left ventricular enlargement; with the rough systolic murmur, and the corresponding thrill‡ at the base transmitted into the neck; a short diastolic murmur in the usual aortic areas of transference, and a high or maintained diastolic pressure; with a history as negative for syphilis and rheumatic infection as we can ever depend upon—we fully expect autopsy confirmation, if such is ever permitted. In all, note that the evidence of aortic insufficiency is definite (a lesion most classically constant with its auscultatory evidence). Further, that the evidence of insufficiency is minimal, while that of aortic stenosis is maximal.

Case 4.—J. V., male, aged 47, was without previous history of specific or non-specific infection. He was seen in October, 1929, with a definite cardiac condition. For eighteen months he had had substernal pain, palpitation and dyspnea on exertion. On occasion there had also been a harsh, non-productive cough.

The chest examination (briefly outlined) is noted on his chart as follows: "Percussion shows a definite left ventricular hypertrophy, without any evident enlargement of the aortic arch. Fluoroscopic inspection brings out the definite globular heart outline, with a maximal left ventricular increase (Fig. 6). Palpation reveals a fine thrill at the third interspace to the right. This thrill is increased after exertion. On auscultation a very rough, grating, blowing systolic murmur is heard best at A2, but is transmitted over the entire precordium and up into the neck. At the third left interspace and at the lower end of the sternum, slightly to the left, there is a fine, short diastolic murmur. At the base this somewhat displaces the second tone. The blood pressures were 150/70. An electrocardiogram showed an inversion of the T-wave in all leads, and some arborization defect (partial block)."

Case 5.—Mrs. T. W., aged 72, the mother of ten children (nine living and well), presented herself first in June, 1930.

She admitted no previous illnesses nor operations; nothing to indicate a rheumatic or luetic infection.

For four years there had been increasing precordial distress, lately becoming more severe and increased on exertion. The two severe spells were epigastric, accompanied by nausea and vomiting, and twice called for hypodermic relief. Invariably, however, the attacks were associated with a choking sensation, coming on with dyspnea and palpitation. Many such attacks came on of late without pain. There was much shortness of breath on exertion.

---

‡It seems these thrills are easily overlooked or their presence minimized. In earlier stages they may not be felt over a very large area. Thus, in our case, the earlier observation entirely omitted any statement as to a thrill. Since this became so all-pervading later it is folly to assume that slight degrees of it had not been overlooked.

A brief summary of the chest findings is hereby abstracted: "Left ventricular enlargement, with the percussion border 12.5 cm. to the left of the midline in the fifth interspace (Fig. 7). On auscultation a slight systolic thrill heard over the precordium and up into the neck, synchronous with a loud, rumbling systolic murmur of like distribution. In the third interspace to the left of the sternal border is a faint, sharp, diastolic murmur. There was normal sinus rhythm. The blood pressures 140/70. There was no edema nor obvious visceral congestion."

A Graham-Cole dye test showed poor filling and sluggish emptying of the gallbladder. The gastrointestinal tract was otherwise roentgenologically negative.

There is a fair presumption here that the heart condition has not accounted for all the distress, particularly the epigastric tenderness and decisive colic. Conversely, the gallbladder condition could not possibly account for the heart outline and the determinative data pertaining to the aortic valves.

Case 6.—Mrs. A. H., aged 62, was seen first in July, 1930. She presented the same negative history as the previous cases. She had been treated previously for a year for heart distress and a tendency to dropsy. Her physician had stressed with her a high systolic blood pressure.

The chest examination again showed the characteristic heart outline (Fig. 8). We found the loud, grating, systolic murmur (heard best at the base and transmitted up into the neck), a soft, short, diastolic murmur heard at the second aortic space to the right and the third interspace to the left of the sternum. There was a totally irregular pulse incidental to auricular fibrillation.

Her blood pressures for the period of hospital observation of two weeks varied between 180/90 and 160/100.

CONCLUSIONS AND SUMMARY

1. Postmortem and clinical cases are presented of greatly enlarged hearts with isolated pathology in the aortic cusps inducing high grade aortic stenosis.
2. Associated with this pathology there has been constantly found an associated (secondary) easily demonstrable aortic insufficiency.
3. The cusp distortion was due to nodular calcium deposits. Mönckeberg's ideas as to the manner of the deposition are discussed.
4. This lesion and resulting syndrome can induce typical angina pectoris attacks in which the coronaries are undisturbed.
5. A discussion is interpolated which emphasizes the importance and value of careful attention to heart outlines and (in clinical cases) presumptive weights. The idea of lifting the ban on the diagnosis of aortic stenoses in the absence of multiple valvulitis and a rheumatic history is suggested.
6. Since no valve lesion can cope with aortic stenosis in thickening and enlarging the left ventricle there is incentive to investigate such very large hearts for determinative evidence of that lesion.
7. Its etiology can be found in *calcareous nodule deposition in aortic cusps.*

OPINIONS OF 470 PHYSICIANS IN REGARD TO THE ADVANTAGES AND DISADVANTAGES OF USING BRAN AND ROUGHAGE*

WALTER C. ALVAREZ, M.D.
Rochester, Minnesota

LAST August, Everybody's Health, the Journal of the Minnesota Public Health Association, published an article in which I asked for a little more thoughtfulness in the prescription of bran and other forms of roughage. I reminded physicians and dietitians that one of the two reasons for giving bran is that it is absolutely indigestible, and I suggested that this fact be thought of more often when attempts are being made to treat constipation in persons who are not strong. If one is sure that the patient has the digestion of an ostrich one can, perhaps, dump into his stomach large quantities of bran, dried seaweed, vegetable fiber, seeds, or cold, indigestible grease, and expect him to handle it all without distress. Examination of the stools later may show that digestion has been much interfered with, but if the patient is sufficiently insensitive he will be unconscious of any abnormality, and if his constipation is relieved he will go on his way rejoicing, and insisting that all his friends do as he has done. But let one of these friends happen to have a weak, easily disturbed digestion, or a bowel in which there are narrowed or highly irritable places, and he may find himself unable to handle the extra mass of indigestible material. In this case there will be flatulence, intestinal unrest and discomfort, and perhaps some loss of weight.

The second reason for the giving of bran and roughage is the delusion or obsession that it is only by eating these substances that one can secure all those vitamins, salts, and mineral elements that are essential to life. Actually, anyone who knows anything at all about the subject knows that these dietary constituents can be obtained in large amounts and in more assimilable form from many other foods; in fact, if it is desirable, they can even be obtained from the drug store.

I fear that the future historian of medicine is going to be somewhat puzzled when he comes to write up the story of the vitamin mania of the twentieth century. He will wonder what on earth could have so frightened the dietitians that they should have behaved each day as if a moment's relaxation of vigilance would plunge all their (adult) patients into the throes of scurvy, beri-beri, pellagra, war edema, and xerophthalmia. Perhaps one reason why they fear these diseases so terribly is that they have never seen them and do not know what they are. Similarly, most people today are horrified at the thought of leprosy because they haven't the least idea what it is.

To show how rare the vitamin deficiency diseases are in America I need only say that in twenty years of consultant practice I have seen only one case of beri-beri (due in part to lack of Vitamin B), and one case of scurvy. I may have failed to recognize some cases, but even at that, these can hardly be diseases which everyone should be worrying about during every hour of the day. There are some physicians, dietitians, Red Cross workers, pediatricians, and others who must worry, but they are the ones who take care of the underfed children of the poor, old half-crazy recluses and men out of work who "batch" in cheap hotel rooms or in backwoods ranch houses, fussy old women who live on tea and toast, men and women with ulcer or colitis who try to live for months on milk and eggs, starving farmers in the drought-stricken areas of the South, winter-bound fishermen on the Labrador Coast, inmates of jails and poorhouses, and particularly the explorers who have to live entirely on preserved food. All such persons who live abnormally are in danger, but, so far as I can see, most of us who have a fair income and who eat as our fellows do can have little to worry about.

Whenever I have been so unfortunate as to get into an argument with a whole-wheat enthusiast of the type who would gladly legislate white bread out of existence, I have met this argument: "But, if you don't eat whole-wheat bread, where are you going to get your vitamins and your iron?" Even professional dietitians have tried to floor me with this question, forgetting for a moment what they must have known, that there are many other and better sources of vitamins and iron besides bran. Furthermore, strange as it may seem to the average dietitian, there is no shadow of an excuse for giving roughage when one wants to supply vitamins or chemical elements. One can get more than enough Vitamin A in butter, more than enough of the two B's in a little yeast or extract of wheat kernel (obtainable in a drug store), more than enough C in a little orange juice, and more than enough D in a little tablet of concentrated cod liver oil or irradiated ergosterol. Iron can be obtained in many foods besides wheat and spinach, and, if desired, can be supplied in the form of pills, just as they are now supplied in the standard salt mixture given to the rats in research laboratories. Even the green chlorophyll of plants can now be obtained in tablet form so that there is no real need for the appearance each day of spinach on every sick-tray in every hospital in the land.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

What I ask of dietitians is that when they are trying to help patients with a poorly functioning digestive tract, one which for a time should be rested and treated kindly, they should give food which is chosen primarily for its digestibility and palatability and only secondarily for its vitamin content. Actually, in most cases, as when a patient is going to be in the hospital for two or three weeks after an operation, it is only a thoughtless or ignorant person who would worry about the vitamin content of the diet. Everyone who eats sensibly has enough vitamins stored in his body to tide him over a few weeks or even months of semi-starvation.

In order to obtain some idea of the views and practices of physicians in regard to the use of bran, and also of their experience with it, the Public Health Education Committee of the Minnesota State Medical Association sent out a large number of questionnaires to physicians all over the United States. The 470 answers that were received have been tabulated in the editorial office of "Everybody's Health," and the summary and the returned sheets have been turned over to me for comment.

Unfortunately, as everyone knows who has ever attempted to answer a questionnaire of the type sent out, it is difficult to make even a good guess as to his experience or his impressions. When, months ago, I tried to fill out the blank sent me, I felt in somewhat the mood of one of Minnesota's ablest women physicians who wrote on the back of her paper: "I think the formulating of this questionnaire and the answering of it is a laughable waste of time. I am answering questions vaguely . . . my statements based on impressions only and influenced by my opinions of what the answer ought to be. I don't *know* a single fact. Now, I feel better after getting that protest out of my system. This seems to me to be no way of getting at knowledge." But with all this handicap I am forced to conclude as I look over the answers that the inquiry has been worth while, and that it has given information of decided interest and value.

Always, of course, with any questionnaire it is impossible to determine whether or not the opinions of the small group who filled out the blank are representative of those of the larger group who dropped it into the wastebasket. Did the men and women who answered do so because they felt a crusading interest for or against the topic discussed? I do not know. What I would suspect is that the few physicians who take time to answer questionnaires are, for the most part, the ablest, the busiest, the most scientifically minded, and the most conscientious in the community; and actually, as I look over the returned blanks I find the signatures of scores of the ablest medical teachers and practitioners in America.

For a moment it was somewhat surprising to find so many of these men expressing themselves as strongly against the use of bran, but then I remembered that it is not the medical profession that has been leading the crusade for the use of more vitamins and roughage; this fight has been waged largely by lay women, amateur dietitians, self-appointed guardians of the public health, and cranks of all kinds.

A number of the physicians who answered made note of the fact that they formerly prescribed bran but later turned strongly against it. Forty per cent said that they never prescribe it, and 34 per cent prescribe it only occasionally. Similarly, 28 per cent do not prescribe whole wheat bread, and 29 per cent prescribe it occasionally. Fifty-seven per cent, when they do prescribe whole wheat, do so because they wish to add roughage to the diet and 41 per cent prescribe it mainly for its vitamin content. There is, of course, some overlapping in the two groups, that is, some men prescribe it for both reasons.

I was interested to see that so many physicians have found that the addition of bran and roughage to the diet will relieve only a small percentage of the patients with constipation. Many of the doctors commented also on the fact that bran may relieve for a time and then fail to have any effect; the bowel seems to become accustomed to the extra stimulus. Only two of the physicians who answered were really enthusiastic about the use of bran for constipation; one was from Arkansas and the other from Michigan; the man from Battle Creek admitted that the substance would relieve probably only from 50 to 70 per cent of the patients with simple constipation. I noted that he left unanswered the question: Have you ever noticed unpleasant results from the use of bran?

I was struck by the letter of one physician who, like many of our profession, amuses himself and gets rid of his spare cash by running a stock farm. He said that it has long been known to stablemen that the horse, even with his powerful digestive tract which has been devised especially for the handling of rough foods and crushed seeds, does not do well if given much bran. He thought that if he had had to stop giving bran to horses, many of us should stop giving it to sick men and women. A number of physicians recorded the observation that many persons who for a time tolerate the use of bran later get into trouble and suffer with indigestion.

I was surprised at the number of physicians who expressed themselves as being strongly opposed to the use of bran. For instance, the president of the American Medical Association (an experienced gastro-enterologist) wrote: "For ten years I have not permitted the use of bran in any family under my direction." I was not surprised to see that three-fourths of the physicians have observed that bran will produce indigestion and flatulence. As I would expect from my own experience, only a few reported cases in which there was loss of weight and still fewer had seen bran produce intestinal obstruction. A number of physicians who see many patients with diabetes, commented on the tendency of bran to produce rectal impaction. One professor of medicine wrote that in his clinic they call it "bran block." A few physicians remembered having seen rare cases of intestinal obstruction due probably to the impaction of bran above a stricture or a carcinoma.

Some physicians reported cases in which inflammatory processes in the bowel appeared to follow the use of bran, but the more thoughtful ones pointed out, what I think is true, that it would be difficult to say of a particular patient whether or not there was any connection between the use of bran and the presence of enteritis or colitis.

Most of the physicians felt that the propaganda for the wide use of roughage has been definitely detrimental to the public health and comfort, and many expressed themselves strongly on the subject. They pointed out that much of this propaganda has been fostered by laymen who have something to sell, and by faddists and cranks who possess neither good judgment nor adequate information. Practically everyone who answered the questionnaire condemned the tendency of school teachers, instructors in home economics, and amateur dietitians to prescribe rough diets for everyone.

Eight per cent of the physicians remembered having seen cases in which they thought cancer of the bowel might have developed as the result of the ingestion of bran, but some of them admitted that they had no real knowledge on the subject.

The part of the questionnaire which interested me most was that in which the physicians reported the extent of their experience (in adults) with diseases due, or supposed to be due, to avitaminosis. Thirty-two per cent said that, so far as they knew, they had never seen an instance of such disease (in adults); 49 per cent had seen a few cases, and 16 per cent had seen a number of cases; 3 per cent did not answer the question.

I was particularly interested to see the answers of the many men with whom I am acquainted and who I know have good judgment and wide experience. Most of these men stated that in the course of years they have seen perhaps two or three cases of scurvy and one or two of pellagra. Some have seen a few cases in the county hospital but none in private practice. A professor of medicine at Harvard wrote on the back of his blank that he had never seen adults with definite vitamin deficiency "unless pernicious anemia is included, and unless pellagra is later proved to be due to a vitamin deficiency." "To me the remarkable thing among adults, to whom my work is confined, is that there is so little, in fact, almost no evidence that vitamin lack plays any part in the illnesses that we see. It seems entirely safe to advise adults to forget vitamins entirely when they are living in the temperate zone and when they are economically able to eat an average diet such as is dictated by hunger and by the sense of taste."

A former professor of medicine at Johns Hopkins answered that he has seen "pellagra? and scurvy occasionally." A teacher of medicine wrote, "I see two types of deficiency, one, a rare, definite case of pellagra or beri-beri or scurvy, and, second, many adults with chronic disease who have profited by a diet rich in all the vitamins, particularly patients with pernicious anemia and chronic arthritis. I cannot determine whether this constitutes a real deficiency of a mixed sort, or whether it is only an incidental finding and one which can be found with equal frequency, perhaps, in normal individuals. The fact that good results follow from forcing vitamins does not necessarily prove an etiological relation." He adds very wisely, "This is a worthy cause you are promoting, but one must take care that propaganda against propaganda does not also end in being unwarrantedly emphatic."

There are, as one would expect, a number of physicians here and there who have become enthusiastic about avitaminosis and who admit, more or less apologetically, that they are now treating all sorts of diseases with high-vitamin diets. Another professor of medicine at Harvard, a man who is particularly interested in problems of nutrition, wrote that he frequently sees cases of beri-beri, pellagra, and scurvy. He is, however, so well known in his field that patients of this type probably come to him from all over the country. The writer of what is perhaps the best textbook on dietetics in the English language wrote in answer to question eight, "Do you ever in adults see cases of definite deficiency?"—"Probably yes, but extremely indefinite." Incidentally he feels that the propaganda for roughage has been highly detrimental.

As was to be expected, many physicians noted that when they do see vitamin deficiency diseases they see them in the very poor, or in the semi-insane, in cranks and faddists who live on freak diets, in those who are inclined to live on alcohol, in persons with anorexia nervosa, in old persons who live alone, in women who try to reduce unwisely, and in persons who live for a long time on restricted diets designed to cure ulcer, nephritis, or diabetes. One physician in New York wrote that in all the years of his practice he has seen but one case of scurvy, and that was in a man who lived on nothing but bread and tea. A physician in Texas reported having seen a few cases of scurvy among ranchers who live out in the mountains and who depend largely on canned food.

I was interested to see that a physician who has had an enormous experience with patients with arthritis, answered question eight in regard to the frequency with which deficiency diseases are seen, with the statement, "Not clearly." One of the world's leading experts on diabetes answered, "No." A professor of medicine in Chicago wrote, "Yes; impression only, no definite knowledge." Another professor of medicine in Chicago wrote: "Rare in private practice; occasionally in the county hospital." Another able clinician said: "I think I do rarely, as in cases of ulcer." Another professor of medicine whose particular interest is gastro-enterology wrote: "Rarely, and then among the poor. I have seen two cases develop during treatment for ulcerative colitis." Another professor of medicine, who is a national authority on problems of nutrition, wrote, "Very rarely." One physician unknown to me, but evidently an enthusiast, wrote, "Daily, all types."

Another physician who has written a textbook on gastro-enterology wrote: "Vitamins are overdone and over-emotionalized at the present time. I do not believe that I can recognize this condition if it exists." One of the ablest physicians in the Northwest wrote that he has seen one case! Another physician, who has had perhaps the largest experience in internal medicine in the Northwest, remembered having seen three cases of pellagra. One of the ablest and busiest internists in Minnesota wrote, in his characteristically vivid way: "The rarest thing in our practice. In Minnesota it is almost impossible for an adult who is not a 'nut' on diet to miss enough of the needful vitamins. The case for babies and young children, of course, is different." One of his able partners, answering the same question, said, "Not specifically certain." It interested me also to see that those physicians at The Mayo Clinic who answered the questionnaire reported, out of their large experience, only an occasional case of scurvy or pellagra.

As one would expect, most of the reports of disease due to lack of vitamins came from the South, and particularly from the poorer districts of the South, where pellagra is endemic. Even from there, however, it is noteworthy that some physicians reported seeing much pellagra, while others said it was rare. There was only one physician who took a strong stand against my statement that vitamin deficiency diseases are probably rare, but he is from the South, and he admits that he is classifying as avitaminosis any disease in which the patient improves on a diet rich in vitamins. He said, "I have seen hundreds of cases in this category, where general health was markedly improved by the addition of vitamins. Pellagra exists often in this class. In my opinion Alvarez is all wrong. The publication of such a doctrine, which is contrary to the views of those who have done the work, seems harmful to me." Most of the physicians, however, seemed to feel as I do, that although we are probably missing cases of dietary deficiency disease and should be more keenly on the watch for them, we must keep our feet on the ground and must not soar off with the faddists into realms of fancy.

To sum up: this questionnaire has shown clearly that the physicians of this country are not enthusiastic about the use of bran. They realize that it can relieve only a certain number of patients with constipation, and in them the relief is often temporary. Most of the physicians report also having seen indigestion and flatulence caused by the use of bran and other rough foods. In fact, many of them have seen so many instances of this that they now refuse to allow any of their patients with indigestion to take these foods. Almost all agree that the present propaganda for the addition of roughage to the diet has been more harmful than beneficial, and almost to a man they condemn the practice of school nurses and others who prescribe the same rough diet for everyone and who offer prizes for the child who can eat the most spinach.

Finally, I think we can say that, except for a handful of enthusiasts who are riding their avitaminosis hobby rather hard, the physicians of the United States are very rarely seeing in adults any disease which they can ascribe with certainty to a deficiency in diet. Only one exception need be made and this is for those physicians in the South who practice among the poor. Many of them are seeing cases of pellagra, scurvy, and general undernourishment.

It would seem, therefore, that unless times ever get so hard that men and women all over this country come close to the edge of starvation, our hospital dietitians can rest easy, and they can with safety stop stuffing their transient guests with foods rich in vitamins. The time may even come again when a six-months-old infant can nurse happily at his mother's breast without having to stop to drink orange juice and cod liver oil, and to eat spinach. As in the good old days, his mother will eat these substances for him, and perchance, if she doesn't like them overmuch she will get a cow to eat them for her so that she can get the necessary concentrates in the cow's milk.

SOME POINTS IN THE DIFFERENTIAL DIAGNOSIS OF CHEST DISEASES*

J. A. Myers, Ph.D., M.D., and Leila M. Kernkamp, M.D.
Minneapolis

In ancient times most chest conditions were known as consumption or phthisis. There were many kinds of phthisis; in fact as late as the time of Sauvages, 1706-1767, this disease was classified into twenty different kinds. Morton reduced the number to sixteen, Portal to fourteen and Baylc, living from 1774 to 1816, reduced the number to six. Baylc and Laennec were close friends, but Baylc died of tuberculosis the year Laennec presented the stethoscope (1816). With this new device for examination, with a splendid training in anatomy and pathology, and with a wide experience at the postmortem table, Laennec changed the interpretation of physical signs and symptoms of diseases of the chest. He was able to take out of the classification of phthisis much that it formerly contained. He worked out carefully such diseases as gangrene, pneumonias, edema, emphysema, and atrophy of the lungs. He took melanosis from the category of pulmonary phthisis, considering such cases as due to anthracosis, or cancer. He also took cancerous phthisis from pulmonary phthisis. Of course, many of his diagnoses were not made before death, but were based upon autopsy findings.

In the century that has passed since Laennec's death, we have had many developments which have facilitated work in differential diagnosis in the living body. Inoculation methods had been attempted a number of times, but in 1843 Klenke found that he could transmit consumption from persons to animals by inoculating into the bodies of animals tuberculous material from the postmortem table. His work was confirmed and carried much further by Villemin and later by Conheim. In 1882, Koch announced the discovery of the tubercle bacillus and since that time the finding of this organism in suspected material from patients has been an extremely valuable point in differential diagnosis. Other aids in diagnosis such as the patient's history, physical examination, the tuberculin test, the X-ray, the bronchoscope, the microscope and iodized oils are doing much to differentiate non-tuberculous from tuberculous lesions.

From the patient's history one can frequently obtain very definite leads. The occupation is of great importance in certain diseases; for example, a person who works about a farm, particularly with farm animals, may be suffering from actinomycosis or aspergillosis. The granite worker, the coal miner and those in other dusty occupations may be suffering from pneumoconiosis.

Occasionally when no cause can be ascribed to an area of disease in the lung a careful history taker may elicit the fact that shortly before the disease began the patient suffered from a severe attack of choking, perhaps while eating a meal. In such cases the aspiration of foreign body must always be considered.

Following pneumonia, pulmonary abscess and empyema are very common complications, as illustrated by the following case:

O. P., a female, 18 years of age, developed pneumonia and nine months later a diagnosis of tuberculosis was made. She then complained of persistent cough, offensive sputum and loss of weight. She went to a sanatorium for the tuberculous and after three months no evidence of tuberculosis had been found. She was discharged with a diagnosis of pulmonary abscess at the left base.

When we first saw her on the advice of the sanatorium staff artificial pneumothorax was instituted. A large adhesion prevented complete collapse of the left base. Thoracotomy was performed and the adhesion was severed. Artificial pneumothorax was continued two years.

It is now nine years since the pneumothorax was instituted and she is in excellent health.

Not all cases of pneumonia are detected, particularly when serial X-ray examinations are lacking. The person who has an abscess formation of the lung will sometimes give a history of having had a severe attack of influenza with high fever for a few days. In many of such cases the patient actually had pneumonia which

*From the University of Minnesota Chest Clinic and the Minneapolis General Hospital Chest Clinic. Presented before the Red River Valley Medical Society at Thief River Falls, Minnesota, on October 19, 1928, the Cass County Medical Society at Fargo, North Dakota, on November 22, 1929, and the Medical Staff of the Lymanhurst School for Tuberculous Children at Minneapolis, Minnesota.

This paper was prepared with the aid of a grant from the Research Fund of the University of Minnesota.

was undetected. Areas of unresolved pneumonia are also often observed. The patient must be questioned as to any operative procedures which preceded the development of pulmonary disease. Was a tonsillectomy or any dentistry done just before the disease appeared?

History of exposure to disease, particularly to tuberculosis, is of considerable significance. In persons coming from homes where tuberculosis has been known to exist this disease must be considered. One should also bear in mind that a history of exposure to pneumonia is significant. On one occasion we saw five cases of pneumonia develop simultaneously in one family after the death of the father from that disease.

A history of malignancy in some other part of the body, even in one thought to have been operated upon successfully, is important. The following case illustrates this point:

C. F. B., a female, 47 years of age, five years before our examination, had had a pelvic tumor removed. Three years later she began to complain of shortness of breath and cough. Three months before we saw her, 500 c.c. of clear fluid was removed from the right pleural cavity. There had been no loss of weight or strength.

On examination dyspnea was present on slight exertion. Her respiratory rate was 25. There were palpable lymph nodes in the left axilla 2 cm. in diameter.

The chest examination revealed dullness at the right base and bronchial breathing over the same area. Hyperresonance was present in the right axilla where the breath sounds were absent.

The X-ray examination showed a partial pneumothorax at the right base with a small amount of fluid. In the left upper lobe was a shadow strongly suggesting tuberculosis. Subsequent studies, however, led to a diagnosis of metastatic malignancy of the lung (Fig. 1). Deep X-ray therapy was administered, but death occurred about eighteen months after our first examination.

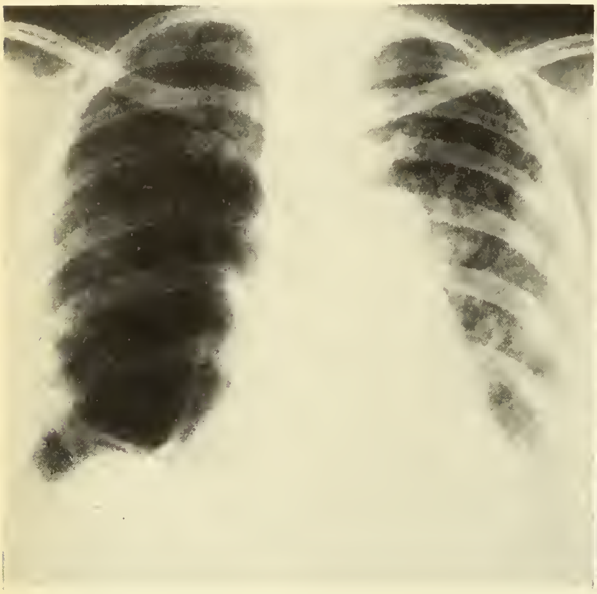

Fig. 1. Roentgenogram of the chest of a woman of forty-seven years, showing spontaneous pneumothorax on the right side with metastatic malignancy involving the left lung.

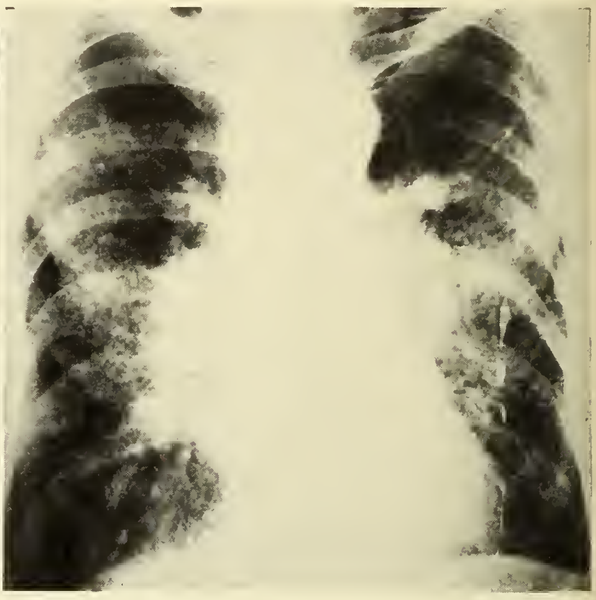

Fig. 2. Roentgenogram of the chest of a man of sixty-seven years, showing metastatic carcinoma involving both lungs.

A history may lead one to suspect carcinoma in some other part of the body, although the most marked present symptoms are referable to the lungs, such as in the following case:

C. A., a male 67 years of age, complained chiefly of dyspnea, but the history revealed the fact that there had been some pain in the epigastrium for one year. He complained of loss of weight and appetite, weakness, belching of gas and occasional vomiting for three months.

On physical examination he was found to be dyspneic, weak and emaciated. The lymph nodes were palpable both in the supraclavicular fossa and in the left axilla. There was a palpable mass in the left upper quadrant of the abdomen.

X-ray of the chest and gastro-intestinal tract revealed evidence of gastric carcinoma with metastases to the lungs and the mediastinum (Fig. 2). Death occurred two months later.

One must not overlook the fact that primary carcinoma of the lung occurs more frequently than we formerly believed. The following case is a good example:

E. P., a male, 34 years of age, had been in excellent health until four months before the first examination. Then he complained of pain in the right chest, loss of appetite, strength and weight, shortness of breath and fever ranging from 99° to 101° F.

The examination revealed limitation of movement on the right side, flatness in the right axilla and dullness over the right chest anteriorly. There was increased whispered voice in the right axilla. No râles were heard. The liver was 3 cm. below the costal margin, but no other abnormal abdominal signs were elicited. There was marked clubbing of the fingers.

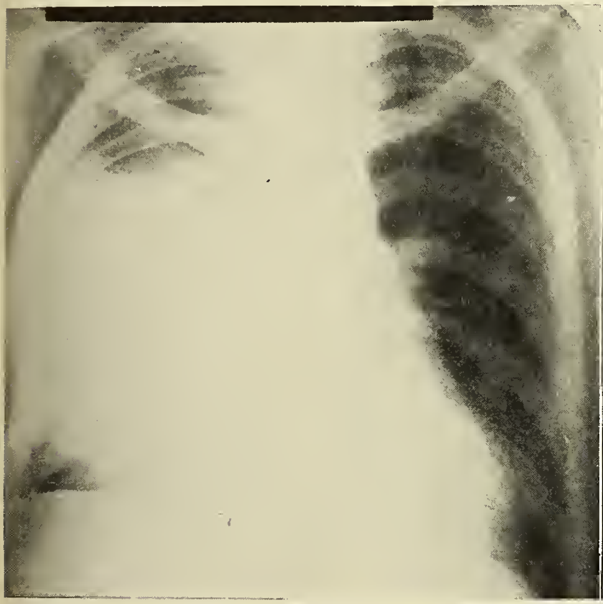

Fig. 3. Roentgenogram of the chest of a man thirty-four years. Postmortem examination showed primary carcinoma of the right lung with metastasis to the regional lymph nodes.

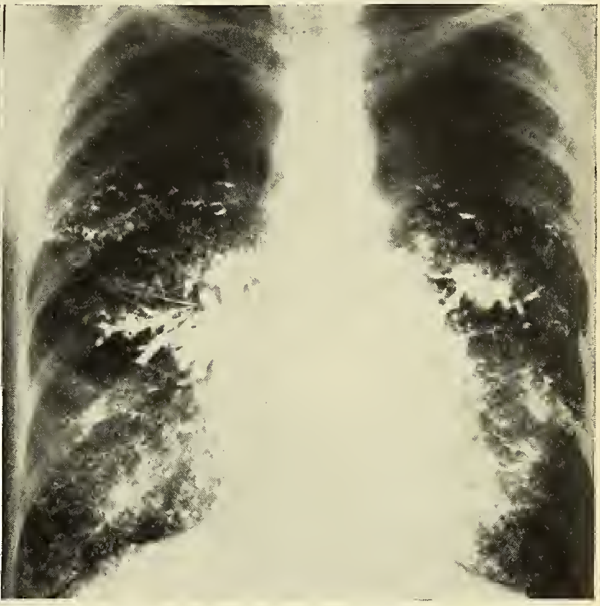

Fig. 4. Roentgenogram of the chest of a woman of thirty-one years after lipiodol had been introduced into each bronchial tree. Case of bronchiectasis.

The X-ray examination revealed what appeared to be a primary new growth arising in right lung (Fig. 3).

Deep X-ray therapy was administered.

The postmortem examination revealed carcinoma of the right lung with metastases into the bronchial lymph nodes on the right side.

Foci of infection of the mouth and upper respiratory tract are often a cause of septic conditions in the lungs, as shown in the following cases:

G. L., a male, twenty-three years of age, for six years had frequent colds and cough with profuse expectoration of purulent odorous material. At times he noticed a numb feeling of the upper jaw. X-rays of the teeth were negative on two occasions.

The chest examination revealed increased whispered voice over the right apex and moderately coarse râles at the right base posteriorly.

The nose and throat examination revealed nasal polyps and bilateral maxillary sinusitis.

The X-ray examination of the chest showed evidence of fibroid tuberculosis of the right middle lobe, but subsequent examinations have led us to believe that this involvement was a non-tuberculous abscess. Bronchiectasis was present in the right lower lobe.

Nasal polyps were removed, submucous resection and maxillary sinus "window" operations were performed. Three abscessed teeth and two carious teeth were removed.

With the removal of these foci of infection two years ago the chest symptoms have gradually disappeared until now he only coughs and expectorates with an occasional "cold."

T. W., a male, forty-two years of age, complained of cough since having ether anesthesia three years before we first saw him. He coughed violently and expectorated profusely. The sputum was purulent and offensive in character. He had changed climate believing tuberculosis to be the cause of his symptoms.

The examination revealed moderately coarse râles over the bases of his lungs, more marked on the right side.

The nose and throat examination revealed bilateral maxillary sinusitis.

The X-ray examination showed evidence of bronchiectasis in both lower lobes, more extensive on the right side.

Permanent openings were established in both maxillary sinuses with great relief of symptoms.

There are no pathognomonic symptoms referable to the chest. Pleurisy may be caused by many conditions, but pleurisy with effusion not preceded by or accompanied by acute respiratory disease is very often due to tuberculosis, perhaps so in ninety to ninety-five per cent of the cases. Hemoptysis is also caused by many conditions. At one time we believed that ninety-five per cent of the pulmonary hemorrhages are due to tuberculosis of the lungs. Observations have shown that patients with bronchiectasis are subjected to hemorrhage more frequently than those with pulmonary tuberculosis. The following cases are good examples:

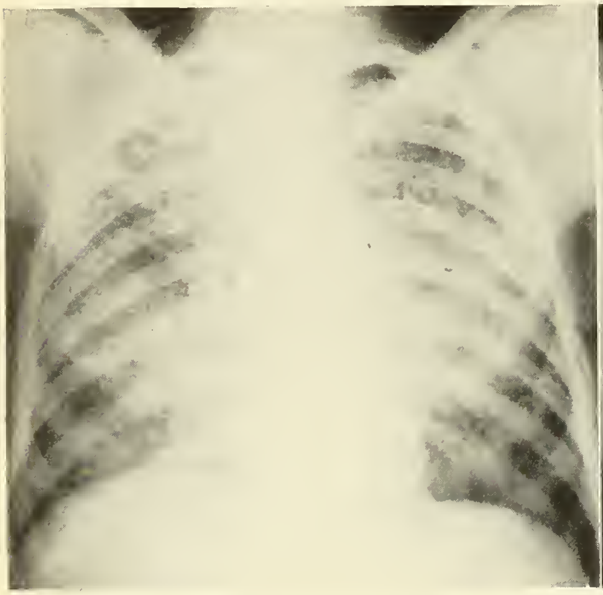

Fig. 5. Roentgenogram of the chest of a man of thirty-two years of age. This shows miliary tuberculosis, involving both lungs. There is an old lesion with cavity formation in the right upper lobe.

A. G., a female, thirty-one years of age, for ten years had a productive cough with profuse, purulent, offensive expectoration, measuring about one cupful a day. One year ago she had a hemorrhage of one-half cup of bright red blood. In the last two months she has had four frank hemorrhages. Ten years ago she had acute rheumatic fever and four years ago she noticed swollen ankles. There has been no swelling since.

The examination revealed a thin, weak and toxic appearing female, with limitation of chest movements. Dullness and râles were present over the base of both lungs.

Her sputum was negative for tubercle bacilli on many examinations.

The X-ray examination following the introduction of iodized oil showed bronchiectatic cavities (Fig. 4).

The paranasal sinuses were clear.

Diagnosis: Bronchiectasis, bilateral.

G. G., a male, forty-two years of age, two weeks after a tonsillectomy performed two years before our first examination, spat up blood and ran a low grade temperature over a period of several weeks. He had frank pulmonary hemorrhages eight different times and had a continuous cough with expectoration. About fifteen months later he had a bronchoscopic examination which revealed bronchiectasis of the left side. Aspiration of the bronchiectatic cavities gave him definite relief. Three months later he began to cough and run a fever. Two months later he had such a severe hemorrhage that he was almost exsanguinated. Artificial pneumothorax was administered on the left side, which immediately controlled the hemorrhage, cough and fever. Three weeks later he developed a bronchial fistula into the left pleural cavity with a resulting empyema. The fistula was valve-like in character, increasing the pressure in the left pleural cavity to such an extent that the heart and mediastinum were pushed to the right, causing great dyspnea and exhaustion. Closed drainage was instituted at once, with slow removal of the fluid. The cavity was irrigated with Dakin's solution every two hours, for twenty-three days, with the exception of five days when normal saline was substituted because of the irritative action of the Dakin's solution in the bronchi. Eleven days after closed drainage was instituted he remained temperature-free and ten days later the pleural cavity was sterile. Since discharge from the hospital two years ago this patient has gradually returned to his activities until now he is carrying on strenuous farm work.

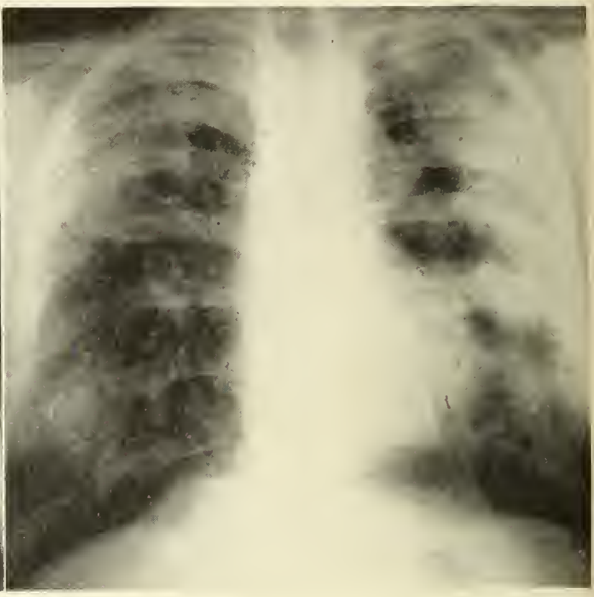

Fig. 6. Roentgenogram of the chest of a man of forty-eight years suffering from pneumoconiosis.

Patients with cardiac disease may also have pulmonary hemorrhages, as shown by the following case:

A. H., female, twenty-one years of age, on two occasions at two weeks intervals spat up bright red blood in an amount of one teaspoonful. She had noticed a slight cough and lassitude for one month.

The examination revealed normal lungs, but there was a systolic thrill and a presystolic murmur transmitted to the left axilla.

The X-ray showed a slight increase of the outline of the left cardiac border. The lungs were normal.

Diagnosis: Mitral stenosis.

Persistent cough is frequently caused by conditions other than tuberculosis. Impacted cerumen may result in paroxysms of coughing. Involvement of the paranasal sinuses very frequently cause cough. When cough is present, there may or may not be sputum. The color of the sputum is of considerable significance. It may vary from clear appearing mucus to a deep yellow or green and in some cases it is streaked or blood tinged. In septic conditions such as lung abscess and bronchiectasis the sputum may have a very foul odor. Again, offensive sputum may be present in cases of pulmonary tuberculosis where it accumulates in cavities and remains over a considerable period of time.

Weight loss occurs in many pulmonary lesions. It is a common symptom in malignancy and pulmonary abscess as well as in tuberculosis. There is not one symptom which is pathognomonic of any chest disease.

In an evaluation of the phases of an examination the relative importance has changed considerably. At one time we placed most emphasis on physical examination. Today, as much as we may dislike to face the fact, we are compelled to place the physical examination below first place.

When the patient presents himself for examination the first time, the intracutaneous tuberculin test should be applied. Although a great deal has been said to the contrary, tuberculin is a very valuable agent in differential diagnosis. This is particularly true since tuberculous infection is no longer universal even in adult life. When definite pulmonary findings are present and the intracutaneous tuberculin test remains negative after the dose has been increased to one or two mg., one can be reasonably certain that a nontuberculous condition exists. In conditions which have been said to reduce hypersensitiveness to tuberculin, such as overwhelming tuberculous disease, and acute febrile diseases, if enough tuberculin is administered a positive reaction will appear. In some cases with negative cutaneous tests it may be necessary to resort to the subcutaneous test. This, when properly applied, is without harm to the patient and gives the physician a good deal of aid in diagnosis.

A. J., female, 29 years of age, complained of cough and expectoration that had been present for many years. She had influenza nine months ago which left her extremely weak and tired. She had an occasional increase in temperature for the last two years and had changed climate, being strongly of the opinion that she had pulmonary tuberculosis.

The chest examination revealed no abnormal signs except a few râles over the bases of her lungs posteriorly.

The X-ray examination was negative, except for accentuation of the bronchial trunks.

The sputum was negative for tubercle bacilli on many occasions.

The basal metabolism was minus 14 per cent.

The cutaneous tuberculin test was negative. We resorted to the subcutaneous tuberculin test administered in the usual manner. She reacted negatively to ten milligrams.

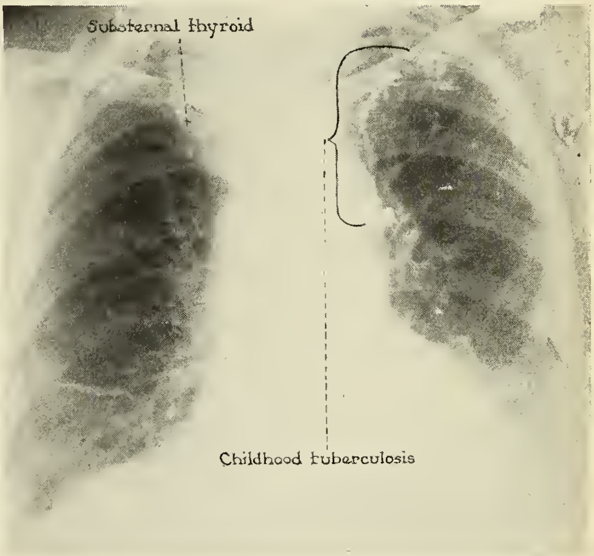

Fig. 7. Roentgenogram of the chest of a woman of sixty-five years. In addition to hypertension heart and substernal thyroid gland, this illustration shows evidence of the childhood type of tuberculosis in the left upper lobe and the left hilum.

In the two years that have passed since this examination, no further symptoms or findings have appeared.

The X-ray has been in use sufficiently long to make it possible for us to give it a very definite place in the evaluation of diagnostic data. We are firmly convinced that a carefully made X-ray examination in the diagnosis of chest conditions is second only to the finding of specific microorganisms. In many cases one cannot rely upon a fluoroscopic examination. A single film of the chest is of considerable value, but is inferior to well-made stereoscopic films when examining for small areas of disease. Such films may reveal evidence of disease in the lung parenchyma before signs are present. If the normal chest is well understood and the stereoscopic films reveal no changes from the normal in the lung parenchyma, one is quite safe in rendering a negative diagnosis of pulmonary pathology. However, it is sometimes necessary to make lateral films in order to visualize areas of the lungs obscured by the heart. This is extremely helpful in questionable cases; it gives one a confidence that is impossible to obtain in any other way. The location of the lesion revealed by the X-ray is also of considerable value in differential diagnosis. Lesions located in the lower part of the lung usually are nontuberculous; those in the middle portion of the lung are about one-half tuberculous; while those in the upper portion of the lungs are usually tuberculous. This does not mean, of course, that a nontuberculous lung abscess may not develop in the upper part of a lung. The X-ray aids greatly in outlining the extent of disease as seen in Figures 5 and 6. Again, it often brings to light unsuspected lesions as shown in Figure 7.

Iodized oil aids the X-ray examination quite materially. It is easily introduced into the bronchial tree, and when all other diagnostic aids have failed, the visualization of the bronchus and its ramifications may aid in diagnosis (Fig. 4).

Improved laboratory methods and the recognition of their great value makes differential diagnosis much easier than in the past. Methods of differentiating between true tubercle bacilli and other acid-fast bacilli are extremely helpful. Concentration methods aid tremendously.

We have come to know that inability to find tubercle bacilli does not mean a great deal unless the search for them has been a long and carefully made one. This is because only approximately one-third of the minimal cases of pulmonary tuberculosis have tubercle bacilli present in the sputum. In other words, there is not sufficient breaking down of the lesion to free bacilli in nearly two-thirds of the early cases of pulmonary tuberculosis. Therefore, we must not wait for the finding of tubercle bacilli before beginning treatment, as the patient often has lost his best chances of recovery before they appear in the sputum. The examination for tubercle bacilli must be a very persistent one, as shown in the following case:

A. J., a female, 31 years of age, had influenza six years ago followed by pneumonia with empyema of the left chest. Closed drainage was used. She was symptom-free for one year, when pus was again present in the left chest. Open drainage relieved symptoms. After nine months she developed a severe cough with expectoration of profuse and offensive sputum. Six months were spent in a tuberculosis sanatorium, where tubercle bacilli were not found in either sputum or pleural exudate. One year ago she had twelve pulmonary hemorrhages. Again no tubercle bacilli could be found. Inguinal lymph nodes were removed which proved to be tuberculous. She rested in a sanatorium and was later advised to have thoracoplasty.

Physical examination revealed enlarged cervical and supraclavicular lymph nodes on the right side. There were enlarged, tender lymph nodes in the left axilla and in the inguinal and femoral regions bilaterally. There was limited movement of the left chest. Tactile fremitus and whispered voice were increased, and moderately coarse râles were elicited over the entire left chest. Thirty-six sputum examinations were negative for tubercle bacilli, but the guinea pig inoculation was positive. Five months later the sputum became positive for tubercle bacilli on direct smear. The X-ray then showed evidence of pulmonary tuberculosis in the right upper and lower lobes and thickening of the pleura on the left side. Barium enema under the fluoroscope gave evidence of colitis, which was thought to be tuberculous.

Again, we know that, since paratubercle bacilli are abundantly present in nature, we must be extremely careful about making diagnoses on the presence of a few acid-fast bacilli in the absence of any other finding. One or two positive sputum reports may be made in cases entirely negative to tuberculosis. In addition to paratubercle bacilli, one must keep in mind errors which occur in laboratories. The following case illustrates this point:

W. K., a male, twenty years of age, following an operation for appendicitis a year before our examination, developed pneumonia on the right side. Convalescence was extremely slow and finally a diagnosis of tuberculosis was made, and he was sent to a sanatorium, where tubercle bacilli were reported from sputum examinations on two occasions.

On examination, after he had spent twelve months in a sanatorium, râles persisting after cough were elicited in the right axilla and right base posteriorly. The left lung was clear.

The X-ray film showed no evidence of tuberculosis. The slight shadows in the right lower lobe were suggestive of an old lung abscess. The sputum was negative on many occasions.

Diagnosis: Pulmonary abscess following pneumonia.

Since our examination this patient has been engaged in strenuous physical work for three years with no recurrence of symptoms.

Careful investigation of the sputum for various kinds of microörganisms often leads to diagnoses of nontuberculous conditions, such as pulmonary distomiasis, actinomycosis, aspergillosis and oidiomycosis. Stovall and Bubolz have recently reported the finding of forty strains of yeast-like fungi isolated from sputum. Lemon has called attention to coccidioidal granuloma being more widespread than is currently believed.

Sayers and Meriwether selected from 18,000 roentgenograms 125 with unusual appearances and which were variously interpreted as being the result of miliary tuberculosis, silicosis, tuberculosis or pneumomycosis. With two exceptions, the subjects appeared healthy. Tubercle bacilli were found in only two cases of eighty-eight in which the sputum examination was made. Fungi were found in the sputum of many cases. The fungi were identified as asperigillus fumigatus fisheri and asperigillus niger. All but one of the 125 cases were associated directly with farming or the handling of grain such as wheat.

The newer modifications for elastic fiber staining are helpful, since elastic fibers in the sputum, accompanying tubercle bacilli, always indicate a pathologically active tuberculous process. On the other hand, the presence of elastic fibers and the absence of tubercle bacilli over a considerable period of time is very strong evidence of the existence of a nontuberculous pulmonary process.

The bronchoscope has been of great help in differential diagnosis and its more general use promises to further aid in differentiating other conditions from tuberculosis. This method makes it possible to actually visualize the inner parts of the trachea, the bronchi and some of their larger ramifications. It also makes biopsy possible in some questionable cases. It is significant that in the past few years primary carcinoma has been detected by this method by Vinson, Moersch and others in a surprisingly large number of cases. Doubtless in years gone by these would have been diagnosed tuberculosis without postmortem examinations. It is obvious, therefore, that the methods of differential diagnosis, even beginning with Laennec's time, have made it possible to detect many nontuberculous conditions which previously were regarded as tuberculous. No doubt, this has played a considerable role in reducing the mortality from tuberculosis and, in recent years, it must be considered as one of the important factors causing the apparent rapid decline in the tuberculosis death rate.

THE PROBLEM OF THE FUNCTIONAL NERVOUS CASE*

W. H. Hengstler, M.D.
Instructor in Nervous and Mental Diseases, University of Minnesota
Saint Paul

THERE is perhaps nothing in the field of medicine, today, more deserving of consideration than the so-called functional nervous case. To the man practicing general medicine and surgery it presents the picture of many and varied subjective symptoms not substantiated by objective findings: the oft-returning and complaining patient who fails to improve and whose burden of woe falls none too lightly on the shoulders of the harassed but uncomplaining doctor. Drugs, operations and arguments fail in giving relief, and the patient travels around from one to another of us and then descends to the chiropractor's level and to that of various other cults. To the neuro-psychiatrist, these are fascinating cases, because they invoke the study and analysis of personality in all its colors, for a personality which has gone awry can cause just as much, if not more, suffering than any physical disease An exhaustive study of this subject is quite impossible in a brief paper of this kind, but a comprehensive review, touching the high spots, may prove interesting and instructive.

It is in order, first of all, to discuss in a general way the factors which are responsible for producing the functional nervous case. Heredity plays its part—not in the transmission of actual disease or structural defect, but in helping to establish the pattern of personality in the individual. Personality may be defined as the reaction of a person to his environment, and his reaction is going to depend to some extent upon the equipment with which he is born. The so-called "neurotic temperament" is definitely transmitted from parent to child—not always but often—and consists merely in the lack in the offspring of normal resistance to meet the experiences he must encounter in passing through life. This failure of resistance may show itself early—at the age of puberty, when evolution is taking place, or even earlier—or it may hide itself under various masks until the latter part of middle life and become very troublesome during the involutional period. In any event, it is rare for an individual of this type to go through life without some demonstration of his "psychological unfitness."

The next great factor is that of experience. As already pointed out in a previous presentation, there is no way of foretelling just what experiences a person is going to meet in life. No two persons meet exactly the same experiences and no two prsons would react exactly alike to the same experiences, but with heredity as a background, experience becomes a vital factor in disorder of personality, and out of experience rise all the myriad reactions and effective symptoms which so ensnare the patient and make his life unbearable.

Greatest of these is fear. It is undeniably the outstanding symptom—the cornerstone, if you please—of the false structure which is built up in the personality of the individual so affected, and fear is invariably the product of experience—the lasting impression which is gained through some shock, physical or psychic. Fear may show itself early or late, after such shock, but can usually be traced directly to its source. Fear may take many forms, common among which are fear of insanity, fear of syphilis, fear of cancer or tuberculosis, and fear of suicide. A patient, now under our care, was so permeated with the fear of suicide that she would remove implements, such as knives and hatchets, from the house, because the sight of them suggested to her that she might use them to kill herself. There was no desire to die—in fact quite the contrary—but the ever-present fear that she might commit suicide haunted her night and day. Another patient now being treated, a woman of seventy, is obsessed with the fear of cancer. She saw her husband die of cancer fourteen years ago. Twelve years ago she had a breast removed for carcinoma, so she, herself, while in excellent physical health, with not a possibility of malignancy, lies in mental torture engendered entirely through fear of this disease. Less common are other bizarre forms of fear, such as the fear of making mistakes, the fear of going into high places, the fear of being in crowds of people, and that terrible affliction—the inferiority complex. A few years ago, a physician from Iowa consulted us because of his fear of mistakes. He would dispense his medicines to his office patients in the afternoon, and in the evening he would drive miles into the country after them going to their homes to check up what he had given—consumed with an anxiety and fear that he might have given the wrong drug. One could write a volume on fear, itself, for its outstanding position as a symptom in functional nervous cases is unimpeachable.

---

*Read before the Tenth District Medical Society, Eau Claire, Wis., Oct. 2, 1930.

So many other elements enter into the pattern of these cases that to enumerate them or to classify them here is out of the question. The early life of the child, the home environment and the "parent-child" relationships are worthy of mention. Lack of proper discipline, absence of love and compatibility in the home, excessive coddling and petting by fond parents during childhood, or excessive anxiety for the child's welfare on the part of the parents, are all very important. Sex education and sex information, imparted at about the age of puberty, will save many a child from defensive reactions which may cause untold misery later on. Many an adult woman has confessed that she had never lost the sense of shame produced when she first experienced menstruation. Not having been informed of this event by her mother, a lasting impression of shame and inferiority was made, which cropped out from time to time and gave her an unbearable state of mind. Many a youth develops serious personality changes because he believes that nocturnal emissions are evidence of some shameful or defective condition. The subject of masturbation and the false assertion to the child that it will produce insanity often bears fruit in later years as a vitally depressive factor in functional nervous disorders. While we are not particularly Freudian in our viewpoint, nevertheless it cannot be denied that the cause of a great many functional nervous disorders lies in faulty sex-adaptation. The rising generation of today is peculiar in its sophistication in all matters pertaining to sex. Just what has caused this is difficult to say, but the fact remains that our youth of both sexes are very blasé in their attitude towards things that a generation ago were left for those of more mature years. This condition, together with liquor and tobacco and all-night parties, must have its effect on the stabilization of the nervous system of the still-developing boy and girl. Sex-freedom and clandestine sex-indulgence by the young people from sixteen to twenty years of age results in premature acquiring of experiences that should be reserved for those somewhat older. This, in turn, tears down "moral fiber" and causes fears and repressions and shame, which produce defensive reactions of various kinds, which we commonly see. We have seen a girl of eighteen develop an hysterical paralysis of bladder and both lower limbs, through fear of pregnancy following sex-indulgen with a married man, and augmented by the fear that her parents would find it out and disown her. We have seen a woman of fifty, who was profoundly depressed because years ago she had tasted clandestine sex-life. We have, at the present time, under observation, a young unmarried woman of thirty-two, who has an overpowering sense of shame and inferiority because "no one wants her." Filled with normal maternal instinct and denied her own children, she lavishes excessive affection on her mother, as a compensatory measure, and is unable to take a position and work because she gets so weak and tired and her back aches so if she tries it. So we must admit that sexual maladjustment plays a great part in the production of these various disorders. Passing on, we encounter the bachelor and old-maid complex, which causes so much misery during the last two decades of life. Unfortunate indeed is the girl who gives up her own matrimonial prospects to take care of an invalid or incompetent parent and who sacrifices her own life's happiness on the mistaken altar of duty. All goes well, perhaps, until finally the parent dies, leaving her alone at forty-five or fifty. She, deprived of her task, and having no child or husband or other vital interest in life, promptly turns in on herself and develops all sorts of functional or emotional symptoms. Nothing is more pitiable than the bachelor of sixty or more, who has no one but himself to think about. His life work is done and he has no other outlet but consideration of his own grievances and his own infirmities, and so he spends his declining years, gradually becoming an egocentric, depressed and morbid old man. We have, under our care at the present time, a spinster of sixty-five. She is all alone in the world, with a small income derived from a legacy of some years' standing. With no one but herself to think of and with all normal instincts in life denied her, she turns periodically into herself and becomes morbid, anxious, depressed and sleepless, and about once a year comes to us for two or three months of treatment. The treatment consists in placing her in the hospital, among agreeable surroundings, where she can make friends and have personal attention from the nurses, and she invariably improves, gets well and goes home happy, to have another attack the next year.

An apology, perhaps, is necessary for presenting these elementary facts in the preceding paragraphs, but they are presented for a purpose, and that is to call attention to the importance of the background of the individual. To handle successfully the functional nervous case, one must study the individual more than the symptoms. Perhaps the greatest difficulty in handling cases of this kind lies in the length of time it takes, for time must be taken if success is to be achieved. To study the individual requires that we secure a word picture of his life as it really has been. His symptoms are of minor importance, for in the true functional nervous case the symptoms are merely local subjective manifestations of a general condition and have no particular reference to the part of the body where they are located. Too often when a patient complains of "headache," the Doctor hurriedly prescribes an anodyne, when a proper analysis of the complaint would prove it to be a sensation of pressure or constriction, so common in depressed individuals, and not pain at all. The head, the stomach, the heart and the bladder are those parts most frequently complained of. The patient believes he is going to lose his mind or thinks he has a tumor in the brain because of the sensation of pressure in his head, or he believes he has heart disease because of palpitation and distress in the left chest. He often says he cannot lie on his left side in bed, because he chokes or feels his heart beating; or he fears cancer because he has gastric distress and belches or vomits. He thinks he has "kidney-trouble" because he urinates so frequently. A careful history in cases of this kind, with a complete review of the individual's life, is of utmost importance, and while the history is being taken the patient should be studied as a whole. Then follows a complete examination to rule out definitely any organic disease and any possible foci of infection. The diagnosis of "psychoneurosis" should be the last diagnosis made.

Within the past sixty days, the writer has had referred to him two cases which were sent in by their physicians as cases of functional nervous disorder. The one proved, on examination, to have multiple myelomata of the vertebral column, and the other an inoperable carcinoma of the pylorus, gallbladder and liver. In both cases the diagnosis was established clinically and verified at autopsy. We are firm believers in complete and exhaustive examinations to rule out infection and disease. We admit readily that obscure infection and obscure disease will produce the symptoms of the functional neuroses, and we repeat that the diagnosis of functional neurosis should be the last one made, but having excluded disease and infection and having studied the patient and arrived at our conclusion, we do not hesitate to make our diagnosis, for we know that emotional disorder will produce such a multiplicity of subjective symptoms as to simulate almost anything.

Mention of the compensation or litigation neurosis has been omitted purposely from this discussion, because such cases constitute a group in themselves, and are always terminated successfully by adjustment of compensation or ending the litigation. As such, they have no place in this presentation.

Turning our attention to the treatment of the functional nervous case, we enter a great field of endeavor which presents innumerable problems of detail, but which, nevertheless, is sponsored by definite and well-balanced principles. From the standpoint of treatment, these cases fall into two large groups:

1. Those not disabled as far as vocation is concerned.

2. Those so affected that they are no longer useful members of society, and are unable to follow their normal occupation.

General principles of treatment are the same in both groups but the details differ. It is with the severely affected type that we are chiefly concerned—those who are so out of adjustment, psychologically, that they can no longer earn a living or balance themselves emotionally so as to fill their normal place in life. To treat such a case successfully in the home or as an office patient is impossible. Surrounded by friends or relatives, the patient is unable to free himself from the emotional morass into which he has sunk, and anything the physician can do either in the office or by calling at the home is promptly neutralized by the home reactions. It is a waste of time to try such a procedure and can end only in disgust on the part of the doctor and failure on the part of the patient. Sending away on a trip rarely does good, for an individual overwhelmed by an emotional tornado in Minnesota or Wisconsin, is not going to be any different in California or Florida. It is no more possible to run away and lose this condition than it is to run away and leave one's shadow behind. The oft-repeated advice to the patient's family to "take him away on a trip and give him a good time" or to get a "change of scenery" is practically worthless from the standpoint of successful therapy. It may prove good in an occasional case, but usually not. The most common effect is to depress the patient more and to discourage the family, because they have tried something that they feel should have succeeded and did not.

The first step needed to insure success is to get the patient away from home and into a hospital or sanitarium. Here a neutral atmosphere can be established and the physician can secure perfect control of his patient and have his orders properly executed. The hospital atmosphere being impersonal and unemotional, offers the ideal field for relaxation and settling down to the business of getting well. The next step is to exclude family and friends and shut off telephone calls and mail. This usually involves an argument with the family as well as with the patient, for they cannot understand the reason for such restrictions. The wise and diplomatic doctor, however, will insist on having his way and will explain to the family that if they are going to the expense of hospitalization to get the sick one away from home, there really is no object in bringing the home to the hospital. Having secured the coöperation of all concerned in these two procedures, the battle is half won. From then on it is up to the doctor to sell himself to the patient and conduct a campaign of education which will result in recovery. This requires time: daily bedside visits, where often it becomes the doctor's job to sit and listen. Having gained the patient's confidence, it is amazing the mass of emotional débris which will pour out of his innermost self, if the physician will sit and listen. Finally comes the time when there is no more material to come and then we begin to see results. Feelings, sensations and experiences which have been repressed, often for years, are removed and the normal personality begins to return in all its buoyancy. Recovery is never rapid. It is usually a matter of many weeks or even months.

Convalescence is punctuated by frequent periods of depression, with return of old fears or the appearance of new ones. This discourages the patient but not the doctor, for these periods grow shorter, less severe and less frequent and there is a gradual and progressive trend towards recovery. With a firm and understanding hand the physician leads his patient, giving explanation and information as often as necessary, and never resorting to ridicule. Many of the most trivial anxieties need the most careful explanations, and under no consideration should the patient be allowed to believe that he is "silly" or "a fool." Ridicule and sarcasm have no place in the treatment of functional nervous cases, and if used will do positive harm and retard recovery, in addition to destroying the confidence of the patient in his doctor.

Physiotherapy, baths, massage and electrotherapy, with many forms of suggestive treatment, are all useful adjuncts. Attention to diet and personal hygiene, with proper regulation of body weight, are also in order. Drugs are given as little as possible, but are used where indicated, particularly to secure adequate sleep at night. Proper adjustment of rest and exercise, with various diversions such as games and occupational therapy, are always proper, particularly during the convalescent period. The hospital or sanitarium régime must be continued until recovery is complete enough to insure self-confidence, and absence of all the former troublesome symptoms.

The physician's personality and his willingness to take the necessary time, together with his ability to read and understand human nature, are the attributes that govern his success in treating the functional nervous case. An accurate diagnosis, a positive attitude, a forceful personality and a real interest in the case will in most instances produce the desired cure.

LEUKOPLAKIC VULVITIS OR KRAUROSIS VULVÆ; ITS RELATION TO CARCINOMA AND ITS SURGICAL TREATMENT*

VIRGIL S. COUNSELLER, M.D.
Rochester, Minnesota

IT hardly seems possible that a disease that was so completely described fifty years ago, a disease which can be present for months or years on the genitalia of women and can produce itching, burning, ulceration, and occasionally can be associated with malignant disease, could still remain the subject of considerable difference of opinion. It does not seem that this disease has been given as much attention in recent years in the literature as its importance merits, although Graves and Smith reviewed the literature and outlined the various views held by gynecologists regarding the terminology and the clinical course of the disease. The five-year results in cases of leukoplakia vulvitis and carcinoma of the vulva recently given by Taussig leave one with scarcely a doubt regarding the correct treatment.

There has always been difference of opinion regarding the terminology of this vulvar disease, and its relation to malignant growth. Most authors have used the terms "leukoplakic vulvitis" and "kraurosis vulvæ" interchangeably, although a few have maintained that the two terms denote separate diseases. Berkeley and Bonney held to the latter view. They stated: "Leukoplakic vulvitis is a chronic inflammatory condition of unknown origin characterized in its early stages by marked hyperemia and cellular activity, and in its later phases by marked epithelial hypertrophy, and a thickened, sclerosed and retracted condition of the subepithelial tissue. The whole of the vulva may be implicated with the exception of the vestibule and orifice of the urethra, which are never affected. It may extend laterally to the folds of the thigh and posteriorly to the external perineum and the skin around the anus." The term kraurosis, which is extensively used in this country to apply to the condition just described, was rejected by Berkeley and Bonney, and was used by them to designate a condition which most gynecologists ordinarily regard as progressive sclerotic genital atrophy. Kraurosis, in the strict sense, as stated by Berkeley and Bonney, is an atrophic condition of the vulva associated chiefly with stenosis of the vaginal orifice and pathologically with certain changes in the dermis. It may involve all the surfaces of the vulva as far as the cutaneous borders of the labia majora, and the skin of the perineum and anal region. They regarded the loss of ovarian function, such as that in young, sterile women, and that following the menopause and surgical removal of the ovaries, as the main etiologic factors in kraurosis, although they admitted the influence of chronic inflammation.

Graves and Smith, from their histologic studies of eighteen cases, regarded leukoplakia vulvitis and kraurosis vulvæ as phases of an identical process, and advocated retaining the term kraurosis in its original sense as described by Breisky. Szàsz and Veit expressed the belief that kraurosis is an end-product of leukoplakia, that the two are different stages of an identical process, and that leukoplakia is a hypertrophic or progressive stage and kraurosis an atrophic or regressive stage. Taussig discarded the term kraurosis entirely and recommended that if it were used at all it should be applied to the simple form of vulvar atrophy, as advocated by Berkeley and Bonney, and that the name leukoplakia vulvitis be used to designate a disease commonly known as kraurosis. I favor the term leukoplakic vulvitis because it signifies the inflammatory nature of the disease. Furthermore, the process not only involves the vulva but may extend to folds of the thigh, perineum and perianal tissue; vulvar atrophy is usually confined to the vulva.

The etiology of leukoplakic vulvitis is not known. It is thought to be associated with chronic irritating vaginal discharge although this is not entirely correct, since patients have been seen who did not have a history of any irritating vaginal secretions. The average age at which the condition makes its appearance is usually in the fifth decade, but it has occurred as early as the thirtieth year and as late as the seventieth year. The average age as given by Berkeley and Bonney is fifty-one years, by Taussig as forty-nine years, and by Graves and Smith as fifty-five and six-tenths years. It is rarely seen in negresses. The civil state of the patient may have a direct bearing on the cause of the disease, since the highest percentage of women who suffer from leukoplakic vulvitis either are married or have been married. Parity does not seem to be a factor, since the number of cases seen in sterile women and in those who have had children are about equally divided. Disturbance of the ovarian function has been repeatedly emphasized in the literature, since practically all cases which have been observed and reported have occurred among patients past the menopause. In cases in which the disease was present before the climacteric the patients for years had had some abnormality of the menstrual function, although it was not always severe. Syphilis has no direct connection with the disease although it may be seen in conjunction with it. It may be said that leukoplakia vulvitis is an inflammatory disease due to some injury or interference with the physiologic activity of the surface epithelium of the labia. This disturbance may in the future be shown to be on a basis of vascular change and infection, since there is diminution of the number of blood capillaries and other blood vessels in the subcutaneous tissue and since the condition is always associated with chronic infection.

*From the Division of Surgery, The Mayo Clinic, Rochester, Minnesota. Read before the Second Annual Meeting of the Central Association of Obstetricians and Gynecologists, Excelsior Springs, Missouri, October 11, 1930.

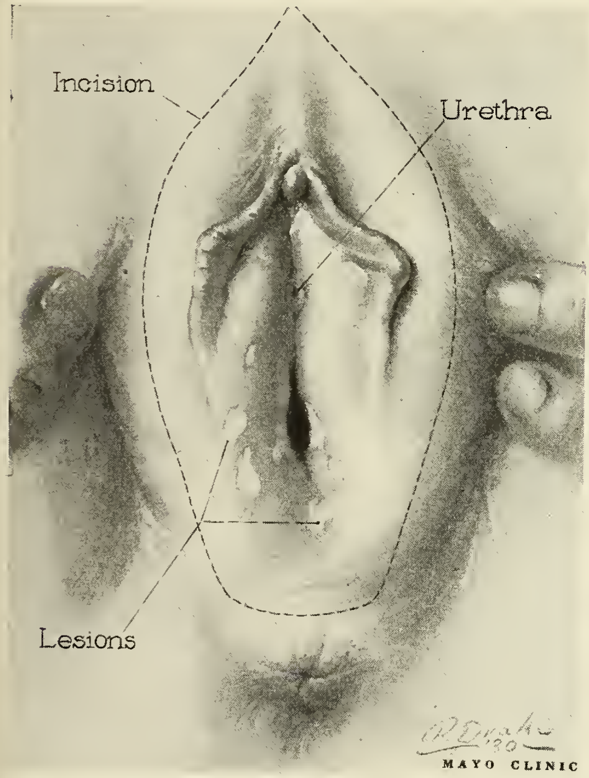

Fig. 1. Leukoplakic vulvitis, early stage, line of incision for simple vulvectomy.

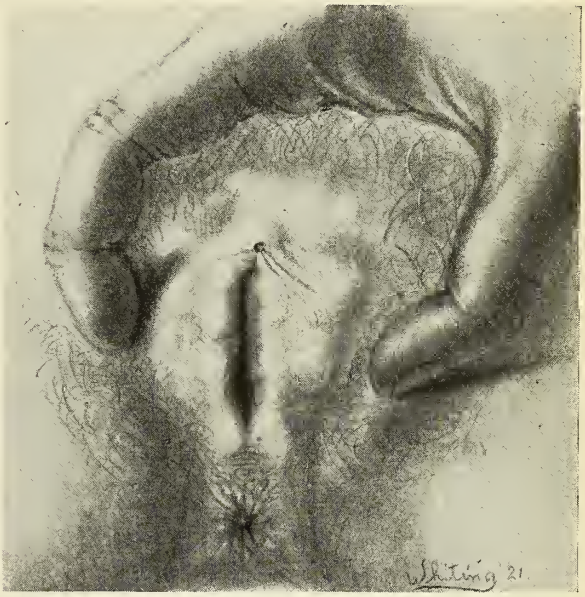

Fig. 2. Leukoplakic vulvitis, late stage. The labia minora are absent and there is marked contraction of the labia majora and partial stenosis of the introitus.

The most characteristic and predominant subjective symptoms are pruritus, burning on urination, and pain or acute sensitiveness of the vulva. The pruritus is of long standing and frequently is the only symptom for many years. It may be so intense that patients suffer from insomnia, for the pruritus is more severe at night. Dysuria is usually worse in the late stages of the disease, when the skin becomes excoriated from scratching. Objectively the vulva is at first reddened, and swollen, and the surface is dry and excoriated (Fig. 1). Later the labia minora decrease in size, become somewhat stiffened, and the color changes from red to white or gray (Fig. 2). The skin then may become cracked and ulcerated, may bleed easily when scratched and there may be a slight discharge on the surface. The ulcers are of various sizes and may be long, irregular or patchy. They may be covered with a pearly blue substance which can be wiped off easily and beneath which is seen a reddened, granulated area. The epithelium around the ulcers is hyperkeratotic and the base is hard and very sensitive to the touch. It is in this hypertrophic or progressive stage that malignancy is said to occur.

If malignancy does not occur, the disease progresses into an atrophic state with marked shrinking and retraction of the parts and stenosis of the vaginal orifice.

The histopathologic picture varies according to the stage in which the disease is seen. The excellent description given by Taussig, who is an authority on vulvar disease, can scarcely be improved. He stated that in the early stage there is seen extensive subepithelial leukocytic infiltration, with pronounced elongation of the epithelial papillæ, and beginning thickening of the keratin layer (Fig. 3). In this layer nuclear elements may be seen, and Taussig applied the term "parakeratosis" to this stage to distinguish it from the later hyperkeratosis, in which only thickly packed fibers of keratin can be seen. After several months, if the disease has been progressive, there is noted a marked increase in the thickness of the eleidin layer and in the amount of eleidin deposited in the cells; the layer appears as a dense black band beneath the keratin layer. The epithelium in the hyperplastic stage is several times thicker than it is in the normal state. There is considerable hyperemia and infiltration of the connective tissue with round cells. In the final or atrophic stage there is marked increase in the connective tissue, associated with sclerosis (Fig. 4). Gradations from the hyperplastic to the atrophic stage can be observed in the same sections, because the changing process is not abrupt. In the late stage there is seen increasing hyperkeratosis, an increased amount of eleidin, and reduction in the size of the epithelial papillæ. These become much flatter and shorter. There is diminution in the infiltration with round cells and increase in the sclerosis of the dermis. Briefly it may be said that in the late stage the epithelial layer consists of a deep layer of hyperkeratosis, beneath which is found a thin layer of eleidin cells, and then, with papillæ absent, a flat strip of pavement cells that may or may not be covered by a single layer of epithelium. The changes in the dermis are perhaps more characteristic. Here the infiltration with round cells is in more or less circumscribed lymphatic zones, which resemble lymph nodes. The infiltration is much less marked than in the early stages, and many plasma and mast cells are scattered through the connective tissue. The connective tissue now undergoes collagenous change, producing patches of glairy tissue in which may be seen but few normal cells (Fig. 5). There is diminution in the amount of elastic tissue between the epithelial papillæ of the skin, and directly beneath the basement membrane, even in the early cases; this absence of elastic fibers becomes increasingly pronounced as the disease advances to the late stage.

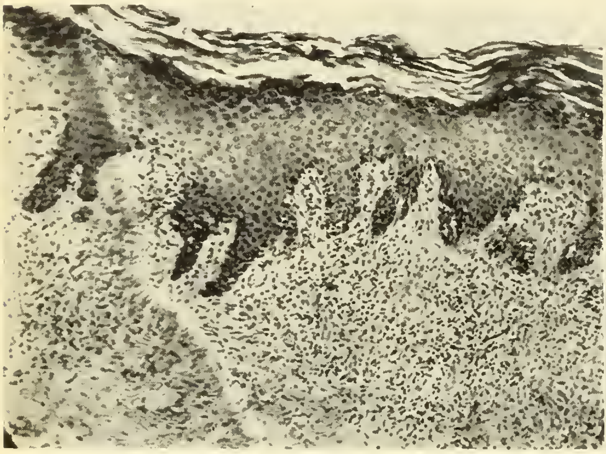

Fig. 3. Elongation of the epithelial papilla, subepithelial leukocytic infiltration and fibrosis with thickening of the keratin layer.

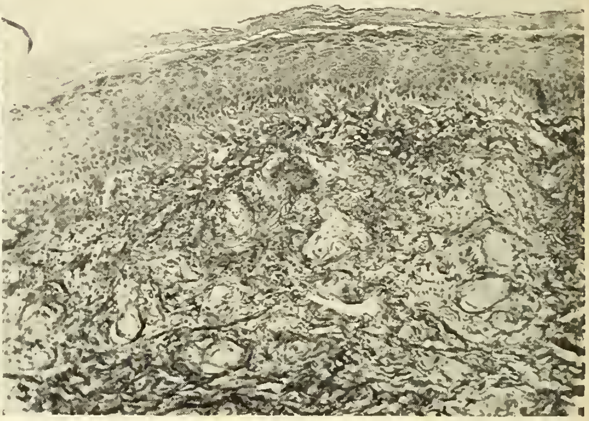

Fig. 4. Van Gieson's stain for connective tissue. Marked subepithelial fibrosis with strangulation of the blood vessels and infection.

RELATIONSHIP OF LEUKOPLAKIC VULVITIS TO MALIGNANT DISEASE

Leukoplakia in its broad sense, since the time of its description by Schwimmer, in 1877, has been regarded as a precursor of carcinoma. Berkeley and Bonney, and Taussig emphasized the tendency of leukoplakic vulvitis to undergo malignant change. Berkeley and Bonney stated that the relationship borne by leukoplakic vulvitis to carcinoma is closer than that of any other pathologic lesion, with the exception of roentgen-ray dermatitis. Mars, Szàsz, Butlin, Schmidt, Bucura, and others described what they considered a direct transition of leukoplakic vulvitis into carcinoma. Kraurosis with carcinoma was reported also by Jung, and recently by Gargert, who mentioned three stages: first, an atrophic kraurotic stage; second, a phase of atypical epithelial proliferation, and third, carcinoma. Smith made an intensive search of his sections in order to determine whether carcinoma developed on a basis of kraurosis as well as on a basis of leukoplakia, in view of the fact that Szàsz expressed the belief that kraurosis is the end-product of leukoplakia, and that kraurosis in its strictest sense represents an entirely obsolete process from which the development of carcinoma is improbable. Smith found that in all but two instances the matrix of the carcinoma was obviously leukoplakic. Taussig found, in a study of thirty-nine cases of vulvar carcinoma which was implanted on a leukoplakic base, that histologically in 60 per cent the malignant changes took place in an early hyperplastic area, and in 40 per cent in a late atrophic area. There seems to be, therefore, sufficient evidence that carcinoma can develop in either stage of the disease although its development is more likely to manifest itself in the hyperplastic or progressive stage. Since carcinoma does not develop in all cases of leukoplakic vulvitis, it would seem that there must be factors other than the leukoplakic process which initiate the malignant process.

Broders stated that leukoplakia is hyperkeratosis and is purely a defensive reaction of the corium; in other words that it is normal thickening of the skin caused by chronic irritation. It may be associated with infection but this depends on the part of the body that is involved. A typical example of hyperkeratosis is the ordinary callus on the hands or that on the soles of the feet. It is frequently seen on the lips of habitual smokers. The itching which develops is induced by infection in the subepithelial tissue. Infection is certainly more likely to occur around the genital and anal orifices, and, once it develops, there is accompanying pruritus of more or less severity which is directly proportional to the amount of infection. Following this there is subepithelial inflammation in addition to leukoplakia, which is aggravated by constant scratching. During the succeeding months or years after the onset a more extensive hyperkeratosis develops. This may spread to the cutaneous margin of the vulva, anal and perineal regions, and may be associated with ulceration and more infection. There is now hyperkeratosis, with thinning of the stratum germinativum and stratum mucosum; marked increase in the number of connective tissue cells, plasma cells, lymphocytes, and mast cells; few polymorphonuclear leukocytes, and decrease in the elastic tissue. This is the classic picture of healing by second intention and scar formation. Katsurada considered this a sign of degeneration, and Frieboes considered it a process of healing by irritation.

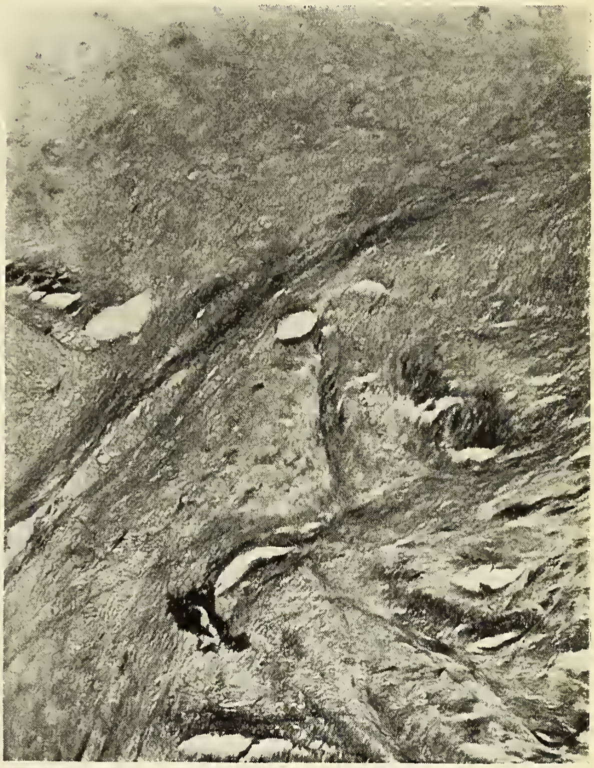

Fig. 5. Late stage. Connective tissue developing collagen, which is a normal protective process. Absence of infection and blood vessels may be noted.

From the onset until the final stage of the disease the most characteristic picture is one of constant increase in connective tissue and decrease of elastic tissue, with strangulation and disappearance of blood vessels, which ultimately ends in atrophy. These same changes may be compared to those seen in portal cirrhosis in which there is (1) infection around the portal spaces, from moderate to severe degree; (2) a deposit of connective tissue around the blood vessels and bile ducts, associated with atrophy of the hepatic tissue, and (3) strangulation of the blood vessels, and scar formation.

In leukoplakic vulvitis there is a moderate degree of activity or regeneration of the stratum germinativum and stratum mucosum which is characterized by extension downward of the epithelium in a papillary manner; this process may be marked, but it is benign. However, this regeneration is not as pronounced as the regeneration of the connective tissue. As the connective tissue increases, a process of retraction and scarring is initiated, together with diminution in the infection. Pruritus then becomes less severe and the disease is said to be quiescent.

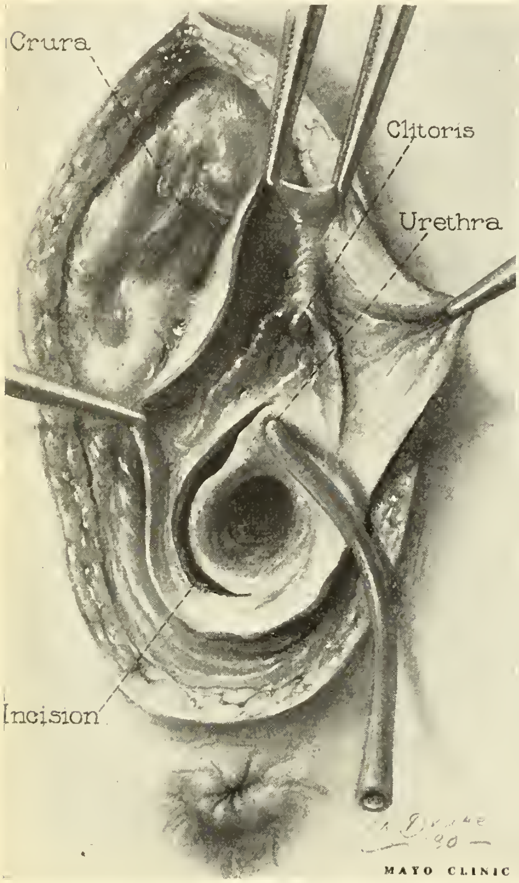

Fig. 6. The inner incision extends around the vaginal orifice at the mucocutaneous juncture and passes anterior to the urethra, thus preserving this structure. The outer incision is completed. The labia majora and minora and the clitoris are removed en masse.

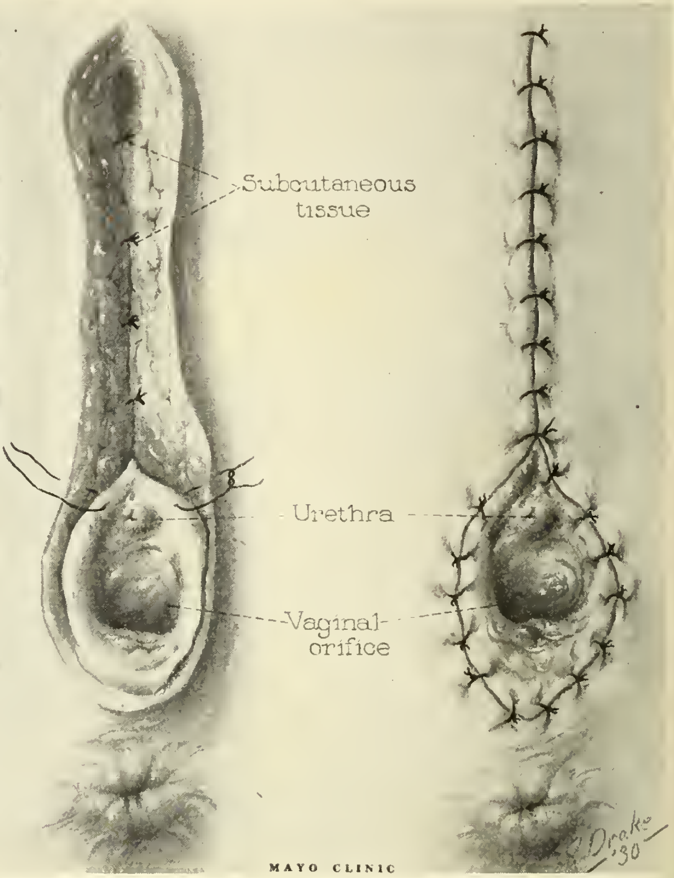

Fig. 7. Closure of the skin and subcutaneous tissue.

In a consideration of the relationship which this disease has to the development of malignant change in the vulva, I believe that all statements must be made with reservation. It is true that epithelioma is seen with leukoplakic vulvitis, but the malignant process usually is the predominant picture. On the other hand, there are epitheliomas of the vulva with little, if any, leukoplakia, and, again, approximately 50 per cent of the cases of leukoplakic vulvitis terminate in complete atrophy of the vulva and stenosis of the vagina. Rentschler, in a review of seventy-one cases of primary epithelioma of the vulva seen at The Mayo Clinic between 1907 and 1927, found that in 40 per cent the patients gave a definite history of preëxisting pruritus but that in only five cases were both leukoplakia and malignant change found pathologically. This, however, cannot be accepted as absolutely correct because a high percentage of the patients had been subjected to various methods of treatment for pruritus, such as ultra-violet light, radium, roentgen rays, and partial excision, before they came to the clinic. Such procedures unquestionably change the histologic picture.

It seems unlikely that the development of carcinoma in a vulva, previously the seat of leukoplakic vulvitis, is the direct consequence of a chronic inflammatory process. If leukoplakia is a precursor of carcinoma of the vulva, then malignant lesions should develop in varicose ulcers and in lesions of blastomycosis, since the same type of epithelium is involved, but they practically never do develop on a basis of such lesions. Carcinoma does not develop in all cases of leukoplakic vulvitis; moreover, carcinoma of the vulva occurs without leukoplakia. These facts seem to indicate that the cause of carcinoma, which accompanies leukoplakia, is not irritation.

Carcinomas of the vulva are, as a rule, slow in growth, and approximately 80 per cent are graded 1 or 2. The epithelial cells are differentiated and produce keratin which tends to hold the malignant process in check. There is also increase in the connective tissue stroma as a consequence of chronic infection. This may explain why the histologic picture resembles leukoplakia or kraurosis. Furthermore, it is rare to find kraurotic changes in a malignant lesion of the vulva graded 3 or 4, because it is developing too rapidly.

TREATMENT

The treatment of leukoplakic vulvitis in the early stages has always been directed toward eradicating the pruritus. This has been done by applying nonirritating emollients, salves, roentgen rays and radium. Most of these agents have only a temporary effect, but roentgen rays and radium often stimulate the disease or may produce a burn. If a malignant lesion is not present the ideal treatment would be obtained by sectioning the internal pudic nerve, thereby anesthetizing the vulva and permanently relieving the pain and pruritus. This procedure was first suggested by Simpson of Edinburgh, in 1861, for vaginismus; it was used, also, by Rochet, in 1899, and again in 1903, in the treatment of painful spasm of the posterior urethra and later in the treatment of pruritus vulvæ. Albertin, in 1903, used it in certain types of painful cystitis; Tavel, in 1902, used it against vaginismus and pruritus vulvæ.

Wertheimer and Michon performed this operation in two cases of vaginismus, in two cases of kraurosis vulvæ and in one case of epithelioma of the vulva. The relief from pain was permanent in the cases of vaginismus and kraurosis, and it was satisfactory in the epithelioma of the vulva. It would seem logical, therefore, in cases of leukoplakic vulvitis, if the ulcerations are not malignant, to advise section of the internal pudic nerve, since it would give permanent relief from the symptoms which make life miserable. Learmonth, of The Mayo Clinic, has performed this operation with very satisfactory results.[14]

Following this operation the patient should be submitted to careful examination at least twice a year, and if there is any question of the presence of a malignant lesion, simple vulvectomy (Figs. 1, 6 and 7) should be performed in cases in which the malignancy is graded 1 or 2. If the malignancy is of a higher grade or if there is lymphatic involvement in a case of malignancy of lower grade, radical vulvectomy with bilateral dissection of the gland-bearing area should be performed after the method of Basset. If the condition of the patient in whom malignancy is found does not justify radical removal, then it would be well to section the internal pudic nerve, and to use radium, as palliative measures.

SUMMARY

Leukoplakic vulvitis is a disease of unknown origin and usually becomes manifest after the menopause. It is a progressive process, lasts for months or years, is characterized by hyperkeratosis, chronic infection and subepithelial fibrosis, and terminates in atrophy of the vulva or it may be associated with malignancy. The relation of leukoplakic vulvitis to carcinoma is not definitely known and will be solved only when the cause of carcinoma is discovered. The treatment in the early stage should consist of section of the internal pudic nerve. In the later stage, if a malignant growth is suspected, vulvectomy should be performed.

O. W. LILLY'S SOLUTION, DENTAL

From an examination made in the A. M. A. Chemical Laboratory it is quite likely that the preparation contains potassium mercuric iodide and an arsenic compound, such as "Solution of Potassium Arsenite U.S.P." (Fowler's Solution). The product is apparently prepared by one Dr. O. W. Lilly of Welch, West Virginia. It is recommended by the proprietor for Vincent's infection and all other acute, infectious, ulcerative conditions of the gums and oral mucosa, infected sockets, and pyorrhea. It is a pity that a mixture of such potent ingredients may be dispensed under a proprietary name to the patient for pathologic conditions of the oral cavity. If a dentist or a physician desires to have his patient use a solution containing a mercury or an arsenic compound, it should be prescribed according to the individual needs, with full appreciation on the part of both prescriber and patient of its poisonous character. (Jour. A. M. A., February 21, 1931, p. 634.)

VITAGLASS

Vitaglass is the trade name for one of many patented ultraviolet transmitting mediums that pass ultraviolet radiations more or less freely. A Bureau of Standards report states that vitaglass of 2.3 mm. thickness has, at a wavelength of 3,020 angstrom units, an average transmitting efficiency of nearly 25 per cent. More recent tests place the efficiency at 42 per cent. Other tests have given an efficiency of 47 per cent. The improvement in the manufacture of the product may account for these varying results. The product varies widely from batch to batch. The purchaser of vitaglass should protect himself by contracting with the dealer to furnish glass where transmission shall, after stabilization of exposure, not fall below the efficiency stated. A recent test gave no indication that children attending school in rooms glazed with vitaglass were perceptibly improved over those children who attended rooms glazed with ordinary glass. (Jour. A. M. A., February 28, 1931, p. 711.)

NON-SPECIFIC VAGINITIS*

William H. Condit, M.D.
Minneapolis

THIS presentation is the result of a study of the records of 230 patients selected from among 43,000 registrations at the Nicollet Clinic of Minneapolis, Minn., upon whom the diagnosis of acute, subacute, or chronic non-specific vaginitis was made. The vagina is provided by nature with certain defenses protecting the peritoneum from infection by way of the uterine canal, the entrance to which may or may not be closed to outside invasion. The chief defense of the vagina is a secretion which, if normal, is destructive to ordinary invading bacteria, and tends to protect the vaginal wall as well as the cervix uteri from infection. Anything that contributes to reducing the natural resistance of this defense, or the nutrition of the vaginal wall, interferes with the protective forces of the vagina and predisposes it to invasion and infection.

Incidence.—It is suggested to the writer that there are many more patients suffering from vaginitis than were encountered ten or fifteen years ago; that is, more in proportion in the aggregate of patients seeking gynecological treatment. Whether the modern dress, mode of living and motor travelling has anything to do with increasing avenues of infection, or whether it is a coincidence of an individual observation, would be difficult to determine. Perhaps prophylactic teachings relative to cancer have brought many to the examining room who otherwise would not have come under observation.

Age.—The youngest of this group of 230 was seven months old; the oldest 78 years. The majority, however, ranged from eighteen to forty, and included unmarried virgins, unmarried individuals who had indulged in sexual intercourse, and married women who had borne one or more children.

Etiology.—The cause of acute, subacute, or chronic vaginitis is usually of bacterial origin; the flagellate trichomona vaginalis also is a common causative agent. The inoculation may be from external contamination or internal systemic infection. The external causes may be trauma, primarily, with an infective process superimposed; infection from the dirt of the streets; soiled douche points; mechanical abuses; accidental inoculation from imperative nursing of anal or rectal afflictions; neglected hygiene; dirty vest pocket or shop soiled condoms, and many less common avenues.

Some no doubt may have existed since infancy and been unnoticed or neglected, lying semi-dormant for years, and fanned into activity in later life, or become more virulent because of lowered general physical resistance from some other disease. If infection by chance invades the vagina one or two days before the actual flow of the menstrual period, when there is a small amount of serum or blood present, a very favorable medium is present for a rapid growth and spread of the infection to the whole vaginal wall. Again, an acute attack may be quite healed with a very few bacteria lying dormant in a fold, mucous cell or gland, when the menstrual flow appears, and a very acute exacerbation will result. It is with apology that I mention focal infection as a possible source of infection, primarily, or secondarily, for nearly all ailments which the human being is heir to are blamed on the much expounded theory of focal infection. However that may be, I have seen rapid recovery take place when the general physical economy has been strengthened by removal of infected tonsils, teeth and appendix. We know the cervix uteri is a highly resistant part of the female anatomy, provided with rich vascular supply, nature having anticipated its receiving much abuse in life. However, we do have definite infections of the cervix and cervical canal resulting from trauma, and infection of its glands from systemic infection above or below. These infections become masked and encapsulated, hidden from external identification, but may act as a store-house of bacteria to pour out infection to the less resistant, weakened vaginal wall. We know that the vagina is a bacterial haven practically from the time of birth. Because of the proximity to the home of the colon bacillus and its numerous relations, that organism is usually found in the vagina. If the colon bacillus secures the upper hand, however, there is no more unpleasant non-virulent organism known as a cause of a most foul-smelling, irritating, profuse vaginitis. Many types of bacteria may be identified in the vagina that has suffered an attack of bacterial invasion, or in a subacute or chronic cervicitis. I have made many attempts to isolate specific organisms without success; in one patient we isolated three unidentifiable organisms from which I made a vaccine, but in general its use was very usatisfactory and discouraging.

---

*From the Department of Obstetrics and Gynecology of the Nicollet Clinic, Minneapolis, Minn. Read before American Association of Obstetricians, Gynecologists and Abdominal Surgeons at Niagara Falls, Ontario, September, 1930.

Pathology.—The gross appearance of the introitus vagina in any type of infection is usually an extremely congested mucosa bathed in a purulent or muco-purulent discharge which usually contains many gas bubbles. The meatus urinarius may be congested and will bleed on the slightest mechanical irritation. The vaginal wall may present the appearance of a congested mucosa, the color and appearance of a very red strawberry with minute bleeding points that give a brown or yellow color to the discharge. Again, the vaginal walls might be compared to a very ripe raspberry, not so bright a red as the "strawberry" type, but with papillary elevations over the entire surface. Not infrequently the inflammation extends over the surface of the cervix uteri and into the cervical canal. It is quite possible, where this condition is present, that the endocervicitis is the primary seat of infection, the process originating from above the canal rather than from without inward. When this situation is encountered, we may have a so-called erosion which will resist therapeutic measures much more than the disease of the vaginal wall, for we have then to deal with a new cell formation resulting from the proliferation of the lymphoid tissue within the cervical canal.

If the vaginitis or cervicitis, or both, have existed for some months, or in many cases for years, we have a hyperplasia of the connective tissue resulting with occlusion of the glands and small cysts developing which add to the discharge pouring from the vaginal mucosa. The cervix then may become hypertrophied to several times its normal size and the vaginal mucosa may also appear much hypertrophied. Abscess formation may occur, but not very frequently.

Pelvic manifestations may be found in thickened tubes and parametrium, especially if the source of infection primarily should be a salpingitis, metritis, or endometritis. An ascending lymphangitis may cause a definite pathology in the ovaries, but it is difficult to estimate just how much this pathology can be traced to an ascending lymphangitis.

Symptomatology.—In forty patients of this series, the trichomona vaginalis was found. The vaginal discharge in patients who suffer from invasion of the above flagellate is very characteristic, has an amber color, a peculiar "burned rag" odor, and is full of tiny gas bubbles. The microscopic examination easily identifies this type and it is very amenable to treatment.

The chief symptoms are a profuse vaginal discharge, usually of an unpleasant or foul odor. The color may be yellow, yellow-greenish, amber or actually bloody. The introitus may be deeply injected and very tender; the skin of the external genitals and legs may be reddened and painful from exposure to continued moisture. The patient may complaint of loss of weight, heavy bearing down sensation in the lower abdomen, general malaise, or even an anxiety neurosis. If the affliction has extended over a period of months or years, there may be bladder symptoms, frequent and painful urination. Constipation may be an accompanying condition, requiring lower bowel therapy and treatment which only adds additional hazard to the vaginal condition, in that additional anal toilet increases chances of contamination of the vagina.

Treatment.—The therapy to select in the treatment of vaginitis will depend upon the age of the patient and the nature of the infection. I treat an infant suffering from an acute vaginal infection by injecting 3 per cent mercurochrome in melted lanolin through a catheter into the vagina, completely filling it, and the patient is confined to bed for forty-eight hours with a tight napkin over the vulva. Nearly as satisfactory results may be obtained by filling the vagina with a 20 per cent solution of arygyrol, or, if the hymenal ring is not too small, by packing the vagina full of a soft gauze strip saturated in 15 per cent argyrol. The patient in either case is confined in bed, and the position is changed so that the solution in the vagina comes in contact with the entire surface of the vaginal wall. In the adult, the secret of treating any infection of the vaginal wall is in exposing the entire surface to the agent employed, obliterating all folds, rugæ, and exposure of all glands. This can be accomplished by packing the vagina full of wool tampons (gauze and cotton is absolutely worthless), thoroughly saturated with the antiseptic agent chosen. The packing should be so tight that the patient will choose the bed for comfort. Our choice of antiseptics has been ichthyol compounds, or mercurochrome solutions and emulsions for the general run of bacterial infections.

The forty patients upon whom a diagnosis of trichomona vaginalis was made were treated either by the "soap alkali" treatment or the "drying-glycerine" method. Greenhill,[2] Davis[1] and Mathieu[3] have so recently provided us with such valuable monographs on this flagellate that anything I might add would be superfluous. The following is the writer's routine method which has given such satisfactory results that I am yet to be convinced of a better method. The whole vaginal wall is dried with gauze, then with an air blast. The vaginal wall is then swabbed with a 10 per cent mercurochrome solution and packed tight with wool tampons saturated with equal parts of glycerine and ichtholdine. Patients are instructed against re-contamination from the anal region, as follows: Never allow a menstrual napkin to slip forward, exert great care in inserting the douche point, and also be careful at intercourse that no organisms be forced into the vagina. Finally, since the usual result of one treatment is immediate relief and since the trichonoma grows rapidly in human blood serum, I instruct the patient on the importance of a vaginal treatment two days pre-menstrual, and two days post-menstrual. My results have been most encouraging.

Remarks.—Careful study of the histories of this series convinced me that twenty-five of the 230 patient (10.8 per cent) suffered from trichonoma vaginalis but were unrecognized. The patients in this group were registered before the year 1924. Our first laboratory report of trichomona findings was in 1921. They were found in dark field examination, accidentally, and were not considered a cause of any pathology.

Records of 65 (28 per cent) of the 230 patients contained definite history of existing focal infection—alveolar, tonsillar, sinus, gallbladder, cervix, appendix, or tubal in the order named. In this series 73 per cent complained of a vaginal discharge on the first visit; the others were discovered in the course of the study of other symptomatology. Eighty-eight, or 38 per cent, were unmarried. Two patients afflicted with trichomona were near the end of third trimester of pregnancy.

NO QUARANTINABLE DISEASE IMPORTED INTO UNITED STATES IN 1930

No instance of the importation into the United States of any quarantinable disease from abroad occurred during the past year. This fact was recorded in a report recently submitted to Congress by Surgeon-General Hugh S. Cumming of the United States Public Health Service. Immunity from such diseases was attributed not only to the system of control at domestic ports but also to the system of medical inspection maintained at foreign ports from which such diseases are likely to spread.

An outbreak of cholera in the Philippine Islands in May, 1930, became so serious that a maritime quarantine against the Islands was established as a means of protection against the transmission of infection, particularly through Oriental steerage passengers to the Hawaiian Islands and the Pacific coast ports of the United States.

Introduction of epidemic cerebrospinal meningitis from Oriental ports was effectually controlled by the continuance of special regulations, prescribed last year, governing the transportation of passengers from such ports to the United States.

The system of medical examination of prospective immigrants in the country of origin, now in effect in the principal European countries, has proved so satisfactory that it is proposed to extend it to other foreign nations.—*Health News,* Mar. 9, 1931.

DIAGNOSIS OF HERPES ZOSTER OPHTHALMICUS*

WALTER H. FINK, M.D., M.S., F.A.C.S.
Minneapolis

HERPES zoster ophthalmicus is an affection of the first division of the trigeminal nerve. It manifests itself by severe neuralgic pain and vesicular formation along the terminal twigs of the nerve supplying the skin of the forehead and ocular structures.

The condition calls for special attention because of the following reasons: it is not rare, it frequently presents diagnostic difficulties which may lead to confusion, and its eye complications may be disastrous. These points are brought out in the three cases presented in this paper. It is also important to emphasize that these cases do not, as a rule, come to the oculist first, but to the family doctor, and the responsibility of diagnosis may rest upon his shoulders.

In general the course is as follows: It is usually seen in people past middle age and begins without apparent cause. Violent neuralgic pains in the eye and forehead precede by several days the appearance of the herpes. The skin is very sensitive and the pain can be controlled only with great difficulty.

After a period of time varying from several hours to days, the skin of the lids and of the forehead becomes red and swollen and upon this area the vesicles appear. The vesicles may be arranged in groups or may be uniformly distributed. They most frequently occupy the region of distribution of the first branch of the trigeminal nerve supplying the upper lid and forehead. It is a characteristic feature of this condition that the affection is almost always confined to one side and does not extend beyond the midline of the head. All of the vesicles may be formed at once, but sometimes they appear in successive crops.

The next step in the course of the condition is that the serous contents of the vesicles become cloudy, then purulent, and finally dry into crusts. This process requires several days, so the period of eruption takes in all about three weeks. As the loss of substance caused by the formation of vesicles extends into the corium, scars are usually left, from the character of which it can long be recognized that the patient has suffered from an attack of herpes zoster. Herpes zoster gangrenosus is produced in rare cases by the spreading of the ulcers in consequence of secondary infection.

The serious aspect of the affection is due to the eye involvement which accompanies it. There is an increased sensitiveness to light and an increased flow of tears. The conjunctiva is affected and vesicles may appear upon it. The cornea may have herpetic eruptions which break down, leaving ulcers, and if they become infected, serious consequences may result. In other cases deep infiltrates develop which may be permanent. Through the paralysis of the trigeminus a neuroparalytic condition of the cornea develops in which there is an absence of sensation on the cornea. An iritis or iridocyclitis may be associated with corneal disease or be independent, and, if not cared for, synechiæ and other disastrous results may follow. Other less frequent findings are scleritis, optic atrophy, lowered intraocular tension and paresis of the abducus and ocular motor nerves which result in defective ocular movement.

Herpes zoster ophthalmicus may lead to difficulties in diagnosis. It may be confused with erysipelas, supra-orbital neuralgia, frontal sinus disease, orbital abscess, migraine headaches, glaucoma, iridocyclitis, ulceration of cornea, and conjunctivitis.

Erysipelas may be considered because of the swollen and reddened condition of the skin and because the lymph-nodes near the ear are swollen; but the arrangement of the vesicles, the fact that the medial line is rarely, if ever, passed over, along with the neuralgic pains, immediately indicates the diagnosis of herpes.

Supra-orbital neuritis is suggested because of the intense pain and is differentiated from herpes because of the lack of redness, swelling of the skin, and later by absence of eruptions and eye symptoms as seen in herpes.

Frontal sinus disease can be diagnosed by the nasal symptoms and findings of acute infection, obstruction, and discharge. The sinus may be cloudy on transillumination or X-ray and relieved by suction. The pain is of a different nature—a pressure pain.

---

*Presented at Asbury Hospital Staff Meeting, Minneapolis, September, 1929

Migraine usually has a history of previous attacks and may be preceded by an aura, may not be unilateral and the pain may extend to the base of the head. There is an absence of redness, swelling, and eruption on the skin.

Glaucoma in the acute stage presents difficulty in diagnosis. In glaucoma the eye symptoms overshadow everything. The pain is intense, the globe extremely tender, the pupil partially dilated and oval, the vision is nil, the congestion of the eye is venous, and the reflex from the pupil greenish.

Iritis due to other causes than herpes zoster may be confused with the iritis of herpes zoster. The diagnosis is not difficult as the pain is not so intense nor so widely distributed. The skin is not affected and it is more gradual in onset than the iritis due to herpes zoster.

Ulcer of the cornea may lead one to think of herpes, but when not associated with it, the pain is not so intense and the cutaneous area not involved. The cause is usually evident.

Conjunctivitis may be extremely painful and cause the lids to swell. However, the presence of pus and the appearance of the conjunctiva are diagnostic.

This very briefly covers some of the conditions which should be thought of when making a diagnosis of herpes zoster ophthalmicus. Herpes can usually be diagnosed at an early stage by elimination.

The following cases emphasize in a more concrete way some of the diagnostic difficulties encountered and complications which may arise. Only the essential facts are mentioned.

Case 1.—The patient was a woman seventy-two years of age, who, previous to the attack, had been in good health. One afternoon she experienced a sense of discomfort in the region of the left eye. This progressively increased in degree and became so intense by evening that a physician was summoned. Local measures were of no avail and when examined a few hours later the patient was in agony and complained of a sharp knife-like pain in the eye and shooting to the forehead. The pain was somewhat lessened by morphine. Examination revealed the lids of the left eye swollen and red, the conjunctiva hyperemic, the eyeball deeply inflamed, the cornea clear, and the pupil rather sluggish in action. The picture suggested most an iridocyclitis, orbital abscess, frontal sinus, or an acute glaucoma. No secretion was present and the tension normal. The picture remained the same for two days and then a reddening and swelling of the skin of the forehead appeared and was sharply limited to the left side. A few hours later vesicles made their appearance, distributed over the forehead and upper lid. The cornea showed several small vesicles which ruptured shortly after, causing ulceration. In spite of all precautions these became infected to a slight degree. The healing process and neuralgic pains continued for months intermittently. The corneal opacities were superficial and gradually disappeared.

This case illustrates the intensity of the onset and the difficulty in early diagnosis. The patient was seen before the eruption and at that time, with only the symptoms of frontal pain and congestion of the eye, it was necessary to differentiate between herpes, glaucoma, supraorbital neuritis, migraine, frontal sinus infection, iritis or iridocyclitis, corneal ulcer, conjunctivitis, and orbital abscess.

Case 2.—The patient was a male sixty-two years of age, with a past history which was not significant. The process started in the usual way with severe ocular pain shooting to the forehead. Because of the redness of the eye the condition was treated as an acute conjunctivitis. As it did not seem to improve, the patient decided to consult the writer. Examination at this time showed an acute iritis with the iris bound down over the pupil area. The vision was almost abolished in the eye and this was of serious importance because the other was blind (an old chorioretinitis). There was no evidence of eruption at this time, which was two days after the onset. Shortly after this, the eruption appeared. By injecting atropine and scopolamin beneath the conjunctiva close to the cornea, the synechiæ were broken enough so that a clear pupil was obtained. The case went on to an uneventful recovery with normal vision, although he still complains at times of knife-like pain in this region.

This case illustrates how a mis-diagnosis may be made and the eye be seriously endangered. The case was not recognized as herpes, the iritis which developed was overlooked and posterior synechiæ developed. This was especially important because the other eye was blind.

Case 3.—The patient was a female, aged 67, who had been in good health. The onset of the condition was not unusual and the usual redness and irritation of the eye appeared after a few days. Complications did not appear until after the eruption, when a cloudiness of the cornea in the central area was noted. This was a deep infiltrate of marked density. No ulceration developed. When seen by the writer the condition had existed several months. There was no improvement on treatment.

This case illustrates how the cornea may become affected without ulceration, resulting in an opacity which may permanently damage the vision.

SUMMARY

Herpes zoster is seen frequently enough in practice to warrant special attention. The condition in the early stage presents difficulties in diagnosis. Disastrous results may follow if the condition is not recognized, because eye complications which develop may lead to serious results if not treated early. The cases presented emphasize this statement.

THE ECONOMIC IMPORTANCE OF SQUINT IN CHILDREN AND ITS EFFECT IN AFTER YEARS*

Frank N. Knapp, M.S.Ophthal., M.D.
Duluth

THE early diagnosis and treatment of incipient tuberculosis has markedly reduced the disability of this disease. The early diagnosis of cancer is the most effective means of saving the life of the patient. The early diagnosis and treatment of squint is equally important if the vision of both eyes is to be preserved. It is very discouraging to see a young adult for the first time and admit that he is beyond the age where it is possible to restore the vision of his crossed eye. With early training the vision in both eyes is retained and the physician and mother are both amply rewarded in being able to send the child into the world with two seeing eyes.

Binocular single vision is the result of fusion of two separate images by the brain centers. Diplopia is the production of two separate images that cannot be fused. Diplopia causes discomfort to the individual. Patients with squint do not complain of diplopia because there is a mental supression of the image from the deviating eye. In all cases of squint, fusion of the image is suppressed for the comfort of the individual. After the suppression of fusion has gone on for a period of time it becomes permanent, with the result that the deviating eye is functionally blind. This loss of vision of one eye is the fundamental question for consideration. Parents are concerned chiefly with the cosmetic result of squint, which is secondary in comparison to the loss of vision. Many parents are astounded as they follow the examination of the child and learn that he has but one useful eye.

Amblyopia of a true congenital type is not the rule. Birth injuries may produce macula lesions with the loss of vision and deviation of one eye. The greatest loss of vision is usually found in cases of convergent squint. In divergent squint there may be a partial loss of the vision of one eye; while in the alternating type the vision is usually equal in both eyes and may be normal.

Worth has tabulated the final visual acuity, after all possible means had been used to improve it, of the deviating eye in 985 cases of constant unilateral convergent squint (Table 1). This summary indicates that squint is not congenital. He has demonstrated that improvement of this defect is possible when the patient is seen before the power of fusion is lost.

Important factors of squint include the age of onset, whether it is the result of an illness or heredity. Many times we will be able to discover visual defects of one eye in either the father or mother. It is true that many cases of squint follow an illness, as measles, chicken-pox or scarlet fever, in which the general health of the patient has been impaired.

All cases of constant squint should be examined for any possible refractive error. No manifest refraction is possible in small children. All cases must be examined objectively after the instillation of atropine for at least three days. For cases of convergent squint nearly a full correction is prescribed. The majority of these patients are far sighted and the use of glasses readily improves the visual acuity. The use of atropine is the essential factor in the examination. It is the author's rule to prescribe glasses for all of these patients as soon as the patient is able to walk. If no improvement is manifest within six months glasses alone will not relieve the squint. The treatment of any squint case is never ended by the prescribing of glasses. Often we see older children who have worn glasses since they were one to three years of age and they later come in with one blind eye and the parents are under the impression that they have done all that is necessary because they have not been instructed otherwise.

There are several ways of improving the vision of the squinting eye. Atropine instilled in the seeing eye paralyzes the accommodation and theoretically compels the patient to use the squinting eye. On the other hand in many cases the vision of the eye under atropine is still better than in the squinting eye and the purpose of the treatment is lost. Sometimes the glass over the straight eye is frosted. This form of treatment usually results in the child removing the glasses and defeats its purpose. The most effective way

of compelling the child to use the squinting eye is to place a bandage with adhesive plaster over the straight eye. This is less easily removed and produces a complete occlusion of the seeing eye. In order to improve the visual acuity of the squinting eye, occlusion training must be carried over a considerable period of time. Asking the mother to bandage the seeing eye for a short time each day is rather ineffective, while if the bandage is worn for a week by intervals marked improvement of the visual acuity in the deviating eye is noted. The purpose of this treatment is well understood by our school nurses and teachers. The teacher's encouragement is a valuable assistance. The prescribing of glasses and the occlusion of one eye are the means at hand for retaining the visual acuity of the squinting eye.

With the deviation of one eye there must be two separate images formed with all its discomfort, or the visual impression of the eye must be suppressed. Suppression is nature's means of relieving double vision in the case of squint. The development of the fusion sense is brought about by the use of the amblyoscope. By this device part of a picture is seen by each eye separately and in order to make a single picture fusion must take place. Ten to fifteen minute exercises each day will stimulate this psychic function.

Some mothers who have sufficient time and take proper interest in the welfare of their child can give these exercises at home. Mothers with large families can not be expected to carry out these exercises. It is even difficult for some patients to come to the office often enough to make this training effective.

In those cases in which visual acuity is not improved by the wearing of glasses and the angle of deviation still persists in spite of glasses, occlusion and fusion training, early operation should be instituted. When the angle of deviation has been eliminated or markedly reduced by operation, further treatment for fusion and improvement of the visual acuity is more effective.

There is an age limit beyond which the treatment of squint becomes ineffective, because after the age of eight or ten years it is quite impossi-

A study has been made of strabismus cases in the Duluth public schools (Table 2). There are 12,253 in the grade schools of the city. Out of this number 288, or 2.75 per cent, are suffering from squint. Of these, 217 are convergent squint. The visual acuities of the squinting eye of 211 of these cases are as follows: vision of 20/20 to 20/40, 119 cases; 20/50 to 20/100, 59 cases; and vision of 20/100 or less, 33 cases. These pupils ranged in age from six to approximately twelve years. It will be noted that less than one-half of them wear glasses. A small percentage of them have been treated by atropine or occlusion of the fixing eye, or by operation. The work of the nurse is difficult because of the indifference on the part of parents. The seriousness of the visual defects of these children might be compared with the visual loss sustained by injury (Table 3). The percentage loss of vision of one eye and compensation as recommended by the Minnesota Academy of Ophthalmology is tabulated. Visual acuity of 20/200 or less is considered industrially blind. A patient industrially blind receives a maximum compensation for one hundred weeks plus a healing period of twenty-five weeks at twenty dollars per week and a minimum fee of eight dollars per week for the same period. Thus for a total loss of vision in one eye a patient would receive a maximum of twenty-five hundred dollars. Injury resulting in reduction of vision to 20/40 by the Snellen type is calculated as 20 per cent loss of vision, which entitles the patient to five hundred dollars. There were in the Duluth public schools this year ninety-two children who have a functual defect of one eye of at least 20/40. The majority of these children are doomed to go through life with only one useful eye. This statement is made because of the facts brought out by a prominent mining company.

A survey (Table 4) of a prominent mining company of 4,424 men is of interest because it includes men of a variety of trades. Of this number there were 277 men (referred to Dr. F. T. Slyfield) with vision of 20/100 or less in one or both eyes. There were sixty-two men with vision of 20/70 or better in one or both eyes. Of 339 there were thirty-four with a vision of 20/100 or less in one eye due to an early squint and loss of vision from disuse. All these men would be unable to gain employment if they were new applicants. Of the thirty-four only nine still had an outward deviation and only six had an internal deviation. On the other hand, in all of the cases of blindness from disuse the visual acuity was less than 20/100 in the previously squinting eye, or, in other words, these men constitute an industrial hazard, because they possess but one functionating eye.

Some of the local industries (Table 5) require visual tests and safe visual acuity is necessary in order to gain employment. The majority of young men who have suffered from squint and the loss of vision of one eye will be unable to gain employment in any of these industries. There will be an ever increasing demand especially for vision by many employers. This places a serious handicap in the case of the boy in the beginning of his career. Many parents if they knew the seriousness of the study would be less indifferent to the welfare of their children's eyes.

As the demand for safety increases, greater stress is placed on the physical ability of employees. Not only are young men being refused employment because of visual defects but old employees must measure up to certain visual requirements. As the result of physical examinations by Dr. F. F. Slyfield (Table 6), from January 1, 1929, to January 1, 1930, there were eleven railroad employees in the city of Duluth with a marked visual defect of one eye from squint sufficient to cost these men their positions.

A young man with defective vision of one eye should never seek employment in a hazardous industry. If by chance the vision of his seeing eye should be destroyed by accident this man is

entitled to compensation for the loss of one eye only and if he is industrially blind in the other eye, whether from squint or any other cause, he is entitled to compensation for permanent total loss of vision which is paid him by the state out of a special fund known as the special compensation fund. Some employers carry their own industrial insurance and they employ safety engineers to eliminate accident. The smaller employer is under a handicap because he has no record of the physical or visual condition of his employees. Following some slight injury the oculist finds a loss of vision often out of proportion to the severity of the injury. Many times he is unable to submit evidence that the eye is blind from a previous squint and disuse.

SUMMARY

1. Effective treatment of squint must be carried out before the school age.
2. Loss of vision of one eye from squint is a serious handicap.
3. No physician should be guilty of advising parents that the child will outgrow the defect.

THE ASSOCIATION OF PEPTIC ULCER AND CHOLECYSTIC DISEASE*

Andrew B. Rivers, M.D.
Division of Medicine, The Mayo Clinic
and
James B. Mason, M.D.
Fellow in Surgery, The Mayo Foundation
Rochester, Minnesota

THE clinician often is chagrined because of the fact that despite a carefully taken history and detailed laboratory procedures he fails to make a preoperative diagnosis of clinically associated lesions of the gastric or biliary tract.

Hartman and Rivers have recently called attention to associated lesions found at operation in 700 cases clinically diagnosed as duodenal ulcer. The most common lesion was chronic appendicitis (44.4 per cent) ; subacute appendicitis, cholecystitis and gastric ulcer occurred infrequently. In 375 cases in which gastric ulcer was clinically diagnosed, chronic appendicitis was the major associated lesion, being found in 35.7 per cent of the cases. Carcinomatous ulcers were found in 2.1 per cent of the cases. They pointed out that if the more commonly associated lesions are borne in mind, a diagnosis may be made correctly oftener if a painstakingly evaluated history is taken.

In contrast to the associated lesions of peptic ulcer, Rivers and Hartman recorded the associated lesions found at operation in 879 cases which were clinically diagnosed cholecystitis or cholelithiasis. Subacute appendicitis was the most common associated lesion discovered (29.5 per cent) ; peptic ulcer was found in only 3.2 per cent. The most significant of the complicating or associated factors discovered during operation was the presence in four cases of carcinoma of the biliary system.

The authors carefully reviewed the case histories but did not find data by which this complication could have been recognized. They concluded that peptic ulcer as a complication of cholecystic disease usually lends itself to diagnosis, that a diagnosis of pancreatitis can only be made tentatively by the surgeon or the clinician, that hepatitis must necessarily be severe before symptoms are manifest, and that a better means of recognizing carcinoma is needed.

Our purpose in making this report is to call attention to the percentage of lesions associated with the different types of operable lesions in the upper right quadrant, regardless of preoperative diagnosis, with the hope of obtaining a correct impression of the actual existence of such associated lesions. The cases were selected for study because the lesions were discovered at the exploration. An attempt was also made to gain, as far as possible, accurate knowledge regarding the actual histopathologic conditions demonstrable in the gallbladder whenever associated disease was found.

MATERIAL USED

The data were obtained from 2,161 operative records. This included 700 cases of duodenal ulcer verified surgically, 435 cases of gastric ulcer, and 1,026 cases of cholecystic disease. Cholecystic disease was found in ninety-five (13.6 per cent) of the cases of duodenal ulcer. In the cases of gastric ulcer pathologic changes were found in the gallbladder or ducts in thirty-four cases (7.8 per cent). In the cases of cholecystitis or cholelithiasis only seventy-three (7.1 per cent) showed evidence of a peptic lesion. The 202 cases including both a peptic ulcer and a lesion in the gallbladder or ducts were studied in detail.

DUODENAL ULCER ASSOCIATED WITH CHOLECYSTIC DISEASE

In ninety-five of the 700 cases of duodenal ulcer in which operation was performed at The Mayo Clinic there was evidence of disease in the gallbladder or ducts.

In a group of forty cases (42 per cent) in which the disease of the gallbladder was eradicated by operation and studied pathologically, the lesions were as follows: chronic cholecystitis with stones in twenty-five cases, chronic cholecystitis without stones in ten cases, subacute

---

*Submitted for publication September 19, 1930.

cholecystitis with stones in four cases, and subacute cholecystitis without stones in one case.

In a group of twenty-six cases (27 per cent) in which removal of the gallbladder was not deemed advisable because of increased surgical risk, the lesions were: a thick-walled gallbladder in sixteen cases, cholecystitis in six cases, benign tumor of the fundus of the gallbladder in two cases, and gallstones in an obviously diseased gallbladder in two cases.

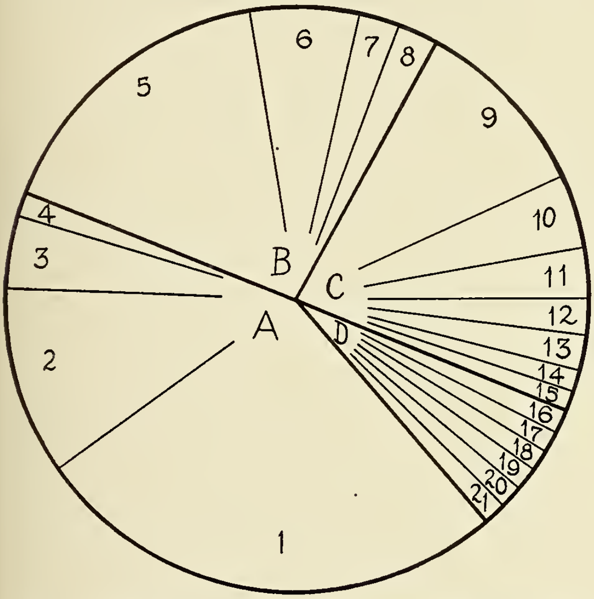

Fig. 1. Duodenal ulcer with cholecystic disease (ninety-five cases). Section A, treated surgically: (1) chronic cholecystitis with stones, twenty-five cases (26.3 per cent); (2) chronic cholecystitis without stones, ten cases (10.5 per cent); (3) subacute cholecystitis with stones, four cases (4.2 per cent), and (4) subacute cholecystitis without stones, one case (1 per cent). Total 42.0 per cent.

Section B, not advisable to treat surgically at this time because of surgical risk: (5) thick-walled gallbladder, sixteen cases (16.3 per cent); (6) cholecystitis present, six cases (6.3 per cent); (7) benign tumor in fundus of gallbladder, two cases (2.1 per cent). and (8) gallstones present, two cases (2.1 per cent). Total 27.4 per cent.

Section C, cholecystic disease suspected from notes taken at operation: (9) "adhesions about gallbladder," ten cases (10.5 per cent); (10) gallbladder "enlarged," four cases (4.2 per cent); (11) gallbladder "distended," three cases (3.2 per cent); (12) gallbladder "tense," two cases (2.1 per cent); (13) gallbladder "not normal color," two cases (2.1 per cent); (14) gallbladder "edematous," one case (1 per cent), and (15) gallbladder perforated through at margin of liver forming hourglass, one case (1 per cent). Total 24.2 per cent.

Section D, Miscellaneous: (16) malignant stricture of the common bile duct, one case (1 per cent); (17) benign mass around neck of the gallbladder and common bile duct, one case (1 per cent); (18) enlarged glands along common bile duct, one case (1 per cent); (19) benign stricture of common bile duct, previous cholecystectomy, one case (1 per cent); (20) negative exploration of the common bile duct, previous cholecystectomy, one case (1 per cent), and (21) residual hepatitis, previous cholecystectomy, one case (1 per cent). Total 6.3 per cent.

In a group of twenty-three cases (24 per cent) in which the surgical diagnosis was questionable, adhesions about the gallbladder were found in ten cases, enlargement of the gallbladder in four cases, distention in three cases, tenseness in two cases, abnormal color in two cases, edema in one case, and hour-glass contraction after the gallbladder had perforated through at the margin of the liver in one case.

In a group of six cases (6 per cent) which could not be included in any of the preceding three groups, the lesions were as follows: malignant stricture of the common bile duct in one case, benign mass in the wall of the gallbladder in one case, enlarged lymph nodes in one case, and (in three cases in which cholecystectomy and subsequently operation for duodenal ulcer were performed) benign stricture of the common bile duct in one case, questionably negative exploration of the common bile duct in one case, and residual hepatitis in one case.

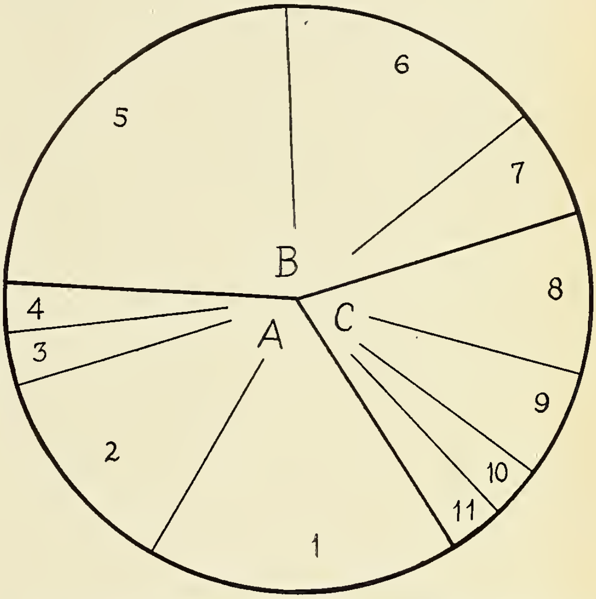

Fig. 2. Gastric ulcer with cholecystic disease (thirty-four cases). Section A, treated surgically: (1) chronic cholecystitis with stones, six cases (17.6 per cent); (2) chronic cholecystitis without stones, four cases (11.8 per cent); (3) subacute cholecystitis with stones, one case (2.9 per cent), and (4) subacute cholecystitis without stones, one case (2.9 per cent). Total 35.2 per cent.

Section B, not advisable to treat surgically at this time because of surgical risk: (5) gallbladder thick-walled, eight cases (23.5 per cent); (6) gallstones present, five cases (14.7 per cent), and (7) cholecystitis present, two cases (5.9 per cent). Total 44.1 per cent.

Section C, cholecystic disease suspected from notes taken at operation: (8) "adhesions about gallbladder," three cases (8.8 per cent); (9) gallbladder "enlarged," two cases (5.9 per cent); (10) gallbladder "tense," one case (2.9 per cent), and (11) "practically a congenital absence of the gallbladder, liver enlarged," one case (2.9 per cent). Total 20.5 per cent.

GASTRIC ULCER ASSOCIATED WITH CHOLECYSTIC DISEASE

In thirty-four of a series of 435 cases of gastric ulcer in which operation was performed and which were known to be benign, disease of the gallbladder was associated.

In a group of twelve cases (35 per cent) operation was performed on the gallbladder. The lesions in this group were as follows: chronic cholecystitis with stones in six cases, cholecystitis without stones in four cases, subacute cholecystitis with stones in one case, and subacute cholecystitis without stones in one case. Removed specimens were studied pathologically.

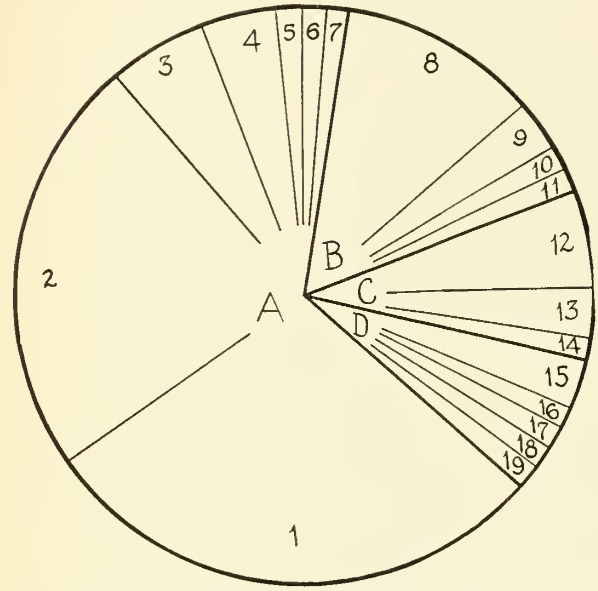

Fig. 3. Cholecystic disease with peptic ulcer (seventy-three cases). Section A, treated surgically: (1) chronic duodenal ulcer, twenty-one cases (28.8 per cent); (2) subacute duodenal ulcer, seventeen cases (23.3 per cent); (3) chronic duodenal ulcer with duodenitis, four cases (5.5 per cent); (4) duodenitis only, three cases (4.1 per cent); (5) jejunal ulcer, previous gastro-enterostomy, one case (1.4 per cent); (6) pyloric obstruction due to ulcer (?), previous excision of gastric ulcer, one case (1.4 per cent), and (7) gastric ulcer, questionable malignancy, one case (1.4 per cent). Total 65.9 per cent.

Section B, not advisable to treat surgically at this time because of surgical risk: (8) chronic duodenal ulcer, eight cases (10.9 per cent); (9) chronic gastric ulcer, two cases (2.7 per cent); (10) ulcerated duodenitis, one case (1.4 per cent), and (11) malignant lesion of the stomach (?), posterior wall at cardia, one case (1.4 per cent). Total 16.4 per cent.

Section C, scar or healed ulcer: (12) scar in duodenum, four cases (5.5 per cent); (13) healed duodenal ulcer, two cases (2.7 per cent), and (14) gastric and duodenal ulcers, both inactive, one case (1.4 per cent). Total 9.6 per cent.

Section D, ulcer suspected from notes taken at operation: (15) duodenum "thick-walled," one case (1.4 per cent); (16) questionable duodenitis, one case (1.4 per cent); (17) questionable duodenal ulcer, one case (1.4 per cent); (18) considerable "inflammatory reaction" in duodenum "in area of gallbladder," one case (1.4 per cent), and (19) thickened pylorus and stomach thick-walled, previous history of obstruction, one case (1.4 per cent). Total 7.0 per cent.

In a group of fifteen cases (44 per cent) the surgeon made a definite anatomic diagnosis of cholecystic disease but did not perform cholecystectomy because of increased surgical risk. The lesions were: thick-walled gallbladder in eight cases, gallstones in five cases, and chronic cholecystitis in two cases.

In a group of seven cases (21 per cent) the surgeon's observation at operation indicated disease or anomalous lesions resident in the gallbladder, as follows: adhesions about the gallbladder in three cases, enlargement of the gallbladder in two cases, tenseness of the gallbladder in one case, and almost complete congenital absence of the gallbladder with enlargement of the liver in one case.

CHOLECYSTIC DISEASE ASSOCIATED WITH PEPTIC ULCER

In seventy-three of a series of 1,026 cases in which operation was performed for cholecystic disease, peptic ulcer was found to be associated.

In a group of forty-eight cases (66 per cent) it was thought advisable to deal with the associated ulcer surgically. An analysis of the ulcers included in this group was as follows: chronic duodenal ulcer in twenty-one cases, subacute duodenal ulcer in seventeen cases, chronic duodenal ulcer with duodenitis in four cases, duodenitis alone in three cases, jejunal ulcer (after posterior gastro-enterostomy) in one case, pyloric obstruction with suspected ulcer in one case, and gastric ulcer which was questionably malignant in one case.

In a group of twelve cases (16 per cent) the surgeon found definite disease of the stomach and duodenum but felt that further surgical procedures were contra-indicated because of increase of the operative risk; in one case surgical procedures were not carried out because of obvious inoperability of the associated lesion. In this group the following lesions were found: chronic duodenal ulcer in eight cases, chronic gastric ulcer in two cases, ulcerated duodenitis in one case, and a probably malignant lesion of the posterior wall of the stomach in one case.

In a group of seven cases (10 per cent) healed gastric or duodenal lesions were found: scar in the duodenum in four cases, healed duodenal ulcer in two cases, and inactive duodenal ulcer and gastric ulcer in one case.

In a group of six cases (8 per cent) the surgical dictation led to the suspicion of an associated ulcer, but this was not definite. The lesions in this group were as follows: questionable duodenal ulcer in one case, questionable duodenitis in one case, a thick-walled duodenum in two cases, considerable inflammatory reaction in the duodenum in the area of the gallbladder in one case, and a thickened pylorus and thick-walled stomach (due to previous obstruction) in one case.

COMMENT

It is sometimes difficult, or even impossible, to make a differential diagnosis of peptic ulcer or of cholecystitis. The association of the two conditions presents further difficulties, it frequently being difficult to determine which disease is responsible for the more serious symptoms. In 37 per cent of the cases of surgically verified subacute or acute duodenal ulcer, the history had sufficient characteristics usually attributed to cholecystic disease to prompt a preoperative diagnosis of associated cholecystic disease, and this, despite the fact that there was definite roentgenologic evidence of duodenal ulcer. In a review of a series of cases[4] in which nonulcerating areal inflammatory duodenal lesions were found at operation, a tendency was noted for the patients to have localizing distress in the upper right quadrant. The probability suggests itself that the pain arising from the duodenal wall itself is felt in the upper right quadrant.

Duodenitis and acute or subacute duodenal ulcer, although likely to mimic disease of the gallbladder, usually have definite characteristics of peptic ulcer in that the distress reaches its maximum several hours after the meal and is relieved by the ingestion of food or soda. The pain may be severe and in both instances may be referred into the thorax. Pain referred through to the back is not uncommon in either cholecystic disease or ulcer, particularly if the latter is a penetrating lesion. It is unusual for the pain of ulcer to be referred to the shoulder, but this is rather a common symptom in diseases of the gallbladder.

In acute or subacute cholecystitis, the area of complaint is usually well localized in the upper right quadrant. There is likely to be tenderness and rigidity in the right infracostal area. Tenderness increases as the palpating finger approaches the lower margin of the ribs. The gallbladder may be paplable. The distress is fairly constant and is not relieved by the ingestion of food. On the contrary, this usually intensifies the symptoms for a brief period. There may be much flatulence and a qualitative food relationship, fats and fried foods being especially likely to intensify symptoms. The syndrome lacks the precision and clock-like regularity of that usually seen in uncomplicated ulcer, and the succession of pain, food and ease is noted several times or many times each day during the period of exacerbation which may last for several weeks.

An icteric or subicteric tint to the skin is frequently noted and a slight elevation of the icterus index or serum bilirubin further tends to localize the disease in the gallbladder or ducts. The vomiting of blood, even in small amounts, or the detection of blood in the stools, is almost certain evidence that the lesion is not in the gallbladder. Roentgenologic investigation may be the deciding factor in making the diagnosis.

The detection of gallstones in the cholecystogram will confirm the diagnosis. Stones becoming impacted in a duct usually produce symptoms sufficiently definite to permit an accurate diagnosis. Even then, there is always the possibility of associated lesions.

The differentiation of chronic disease of the gallbladder with stones or of uncomplicated peptic ulcer is usually not difficult. Blackford and Dwyer called attention to two clinical types of cholecystitis with stones: (1) attacks of gallstone colic for years and then the gradual onset of chronic dyspepsia, and (2) chronic dyspepsia with milder attacks of acute indigestion, often followed by biliary colic. A carefully taken history almost invariably will disclose evidence suggesting the presence of gallstones. The severity of the colic is not so easily forgotten and thus patients as a rule call attention to acute indigestion which they experienced perhaps many years previously.

The pain of gallstone colic usually comes on without much warning and it frequently stops just as quickly, leaving usually, however, residual upper right abdominal tenderness. Often the site of the pain is epigastric, although it may start in the upper right quadrant. Usually it is a deepseated through-and-through pain radiating often into the neck and right shoulder. It is severe, may be lancinating, and is often described "from which there seems to be no escaping except by hypodermics or vomiting." This pain is intensified by associated upper abdominal flatulence which is severe. The breathing seems to be cut off because a deep breath intensifies the symptoms. Emesis occurs at times and the vomitus is usually greenish or yellowish. The attack may terminate quickly, with or without vomiting, but frequently several hypodermics or even an anesthetic may be necessary to obtain control of the pain.

Occasionally transitory fleeting twinges of upper right abdominal pain are noted by patients with gallstones. These pains are likely to be referred into the back. If the gallstone migrates into the common bile duct, chills, fever and jaundice are frequently added to the symptom of pain.

Uncomplicated peptic ulcer includes nothing as a rule which might be confused with the syndrome of gallstones. The symptoms arising from deep penetration of the wall of the duodenum or stomach may simulate the pain of gallstones, but there are many factors which should help in differentiating the two conditions. The history of previous spells of heartburn, distress after meals, and ease from soda and food, all argue for ulcer. The onset of the pain is usually different. In cases of gallstones the onset is rapid, that is, precipitation from comfort to severe pain, and in cases of ulcer the onset is slower. An exception to this is the occasional acute perforation of an ulcer without preliminary indigestion. This may occur following ingestion of an unusually large meal, an alcoholic debauch or excessive exertion. The picture of a patient with a ruptured peptic ulcer is quite characteristic. The pain is usually extremely severe. It usually starts in the epigastrium, whence it is referred into the thorax or back. Occasionally the pain is in the lower right part of the abdomen. It is described as a persistent, deep-seated, sharp, cutting pain intensified by movement or even by respiration. Prostration is marked, and there may be associated nausea and vomiting. There is extreme tenderness over the epigastrium, and characteristic board-like rigidity of the upper part of the abdomen is almost invariably noticeable. Occasionally there is a shifting dulness in the flanks due to the pressure of free fluid. Hepatic dulness may be obliterative.

It is extremely rare that any condition of the gallbladder would simulate the picture of ruptured ulcer, although occasionally an acutely infected gallbladder will rupture, and resulting peritonitis may cause a mistaken diagnosis. Rupture of the gallbladder, except following trauma, always is a later development in the course of cholecystitis, and a carefully taken history should contain evidence wherewith to make a diagnosis. Ruptured ulcer almost always occurs in men; acute cholecystic disease occurs much more commonly in women.

The differential diagnosis of noncomplicated chronic peptic ulcer or of chronic cholecystic disease without stones may be difficult. Not that it is difficult to recognize the presence of active chronic peptic ulcer, but the difficulty as a rule is to be certain that there is no associated disease in the gallbladder. It is important to note that not every duodenal deformity signifies ulcer, that not every duodenal ulcer is active, and that not every active ulcer is the cause of the complaints which activated the patient to obtain relief. Symptoms, therefore, should be evaluated with the greatest thoroughness. An uncomplicated active peptic ulcer usually presents a clear-cut syndrome. Great irregularities in the history suggest that the ulcer, if shown to be present by roentgenologic investigation, may not be active, that the ulcer is complicated in some way, or that there is an associated disease elsewhere in the abdomen. The history may decide the point, or further roentgen-ray study of the gallbladder or colon may make the diagnosis clear. Functional disturbances must be ruled out first by carefully taken histories and proper interpretation of symptoms. Hospital observation and a therapeutic test for ulcer usually are of great help in the making of a correct diagnosis. If patients who have the duodenal deformity attributable to ulcer fail to obtain relief from their symptoms even when the diet is bland, and the gastric acidity is adequately controlled, it may be safe to assume that the ulcer is in some way complicated. Even a perforative type of ulcer is usually relieved by the milk-alkali regimen within four or five days. Persistent upper abdominal distress under these conditions would strongly suggest associated cholecystic disease.

The cholecystogram has been of unquestionable value in helping to detect certain instances of cholecystic disease in which the symptoms were very indefinite and in which a diagnosis preoperatively would have been impossible. The so-called reflex of the gallbladder as a cause of indigestion is extremely indefinite. Clinical syndromes have from time to time been presented which are assumed to be diagnostic of chronic disease of the gallbladder. These syndromes may include indefinite epigastric discomfort, following meals, much upper abdominal flatulence, nausea or vomiting after meals, and belching and bloating after certain types of food such as fats, fried foods, onions, or apples. In our experience such syndromes are unreliable as indications of cholecystic disease. Functional disturbances of the upper part of the digestive tract, constipation, food allergies, and many other conditions are quite as likely to give similar syndromes. There should be some hesitancy in blaming the gallbladder for such syndromes unless the previous history includes localized evidence of more severe and more definite disease in the upper right quadrant.

We have noted the best results following surgical treatment of cholecystic disease in cases in which there was definite clinical evidence of the disease. This is also the observation of Judd, who carefully analyzed the surgical results in various types of cholecystic disease. He found encouraging results in cases in which there were inflammatory changes in the wall of the gallbladder even though these were slight. He stated, however, "If the patient's symptoms were of the chronic dyspeptic type or if the prominent features were soreness, tenderness, and aching in the side, the likelihood of cholecystectomy promoting cure was not great."

There is no doubt that a chronically diseased gallbladder does produce symptoms. The present difficulty seems to arise from attempting to make our syndrome fit the majority of these cases. There are various types of chronic cholecystic disease, and it will become necessary to study these cases separately and carefully to analyze a larger series of histories in each group. Such a study should greatly increase our ability to correlate clinical and histopathologic data, which in turn would obviously increase efficiency in the treatment of cholecystic diseases.

SUMMARY

Evidently cholecystic disease is demonstrable almost twice as frequently in association with duodenal as with gastric ulcer. The propinquity of the duodenum and gallbladder may in part be responsible for this. It is readily conceivable that the inflammatory condition in one organ may extend to and involve to a varying degree the other organ.

Still more striking is the fact that gastric ulcer or thickening in the gastric musculature (gastritis?) was demonstrable as a complication of surgical cholecystic disease only six times in 1,026 cases; benign duodenal lesions were found more than twelve times as commonly as gastric lesions during operation on the gallbladder.

If the relative frequency of these associated conditions is borne in mind, there should be greater accuracy in the proper recognition of such a complication. Not infrequently non-surgical measures instituted for the care of peptic ulcer fail because of the fact that such a lesion is complicated by associated disease in the gallbladder. Every effort should, therefore, be made to make as complete a diagnosis as possible.

UNUSUAL DEFICIENCY SYNDROME SECONDARY TO DUODENAL OCCLUSION AND ULCERATIVE COLITIS

ALBERT M. SNELL, M.D.*
Rochester, Minnesota
and
L. DUDLEY BUMPUS, M.D.**
Grand Rapids, Michigan

IN spite of many precise experimental and clinical studies there is still a great deal of confusion about the exact relationship of the vitamins to deficiency syndromes. Numerous unsuccessful attempts to treat supposed deficiency states with vitamin concentrates indicate that lack of these substances is not alone responsible for the clinical syndrome encountered. This fact is further emphasized by the differences noted between experimental vitamin deficiency and clinical states supposedly due to lack of the same vitamins. Minot, in reviewing the general subject of deficiency disease, called attention to the fact that these conditions are due to a variety of causes, acting individually or combined, and stressed the fact that dietary deficiency syndromes are not always due to lack of vitamins alone, but also to poorly balanced diets, incomplete or low intake of protein, ingestion of an excess of carbohydrate, infection, or altered physiologic mechanisms. When one adopts this broader view of the deficiency syndromes, the probable frequency of abortive, or border-line types of deficiency is at once apparent. The following case is presented to illustrate the multiplicity of symptoms of deficiency disease which may arise from the causes mentioned by Minot.

REPORT OF CASE

A salesman, aged thirty-two years, was admitted to hospital as an emergency case, November 18, 1929. He had traveled to Rochester alone in his car and had collapsed in a local restaurant. On his dmission to the hospital he was extremely weak, dehydrated, and in a state bordering on shock. After he had been revived, the following history was obtained: In 1914 he had suffered an attack of acute appendicitis and operation was advised, but he declined to have this done and recovered uneventfully. Following this he became extremely constipated, and shortly afterward he had an attack of marked abdominal cramping, nausea, and vomiting following the eating of over-ripe fruit. After this episode, which lasted for about three days, he never had been entirely well. Immediately after each meal he suffered with epigastric pain, from which he obtained relief by induced vomiting. He was repeatedly awakened at night by epigastric pain and always obtained relief by emptying his stomach. He had never been relieved by the use of food or soda. From 1914 to 1916 he lost about 35 pounds in weight, chiefly because of a voluntarily restricted diet of soft foods and liquids, and he became so weak that it was impossible for him to continue with his work. In 1917 a roentgenogram had been taken of the stomach, which revealed gastric ulcer with hourglass deformity. Since medical treatment did not produce improvement the patient was advised to have surgical treatment, but declined. Later, however, his symptoms became so much worse that he consented to operation. He stated that the surgeon was unable to do anything to correct the condition which was found in the stomach at the time, and that he was advised to "build up" before any further radical treatment be attempted. In 1918 another attempt at surgical treatment was made. At this time a gastric ulcer was found and gastro-enterostomy was performed. Immediately after the operation very troublesome diarrhea developed and the patient passed from four to six stools daily over a period of about two years. The epigastric pain had been relieved somewhat by the operation and he no longer vomited, but he suffered more or less constantly with abdominal cramps, and, because of the persistent diarrhea, became very weak. Under treatment the diarrhea gradually subsided, and from 1922 to 1928 the patient was in fair health and was able to follow his usual occupation. In 1928 he again began to have attacks of diarrhea, considerably more severe than those which had occurred previously. He passed about ten to fifteen loose stools a day, which frequently contained mucus and occasionally blood. He again restricted his diet, taking practically no fruits or vegetables, and very little milk. As a result of the dietary restriction and diarrhea he lost weight and strength rapidly. He noted particularly that his legs were weak and that he walked with considerable difficulty. In August, 1929, his left leg began to swell; the swelling quickly extended to the right leg and later involved the genitals and abdomen. During this period, he noted deepening color of the skin. His principal complaints on admission were of diarrhea, anorexia, and extreme weakness.

---

*From the Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

**Former Fellow in Medicine, The Mayo Foundation.

The patient was seen to be very weak, dehydrated, and cachectic. There was pronounced pigmentation of the skin, most marked over the extremities and bony prominences. There was no sharp line of demarcation, such as is usually seen in pellagra, but the lesions were otherwise suggestive of it. A scaly, pigmented eruption was noted about the genitals. There was a good deal of edema of the lower extremities and back, and the abdomen was moderately distended with fluid (Fig. 1). The tongue was red, glazed, and somewhat atrophic. Only a few teeth remained and there was no adequate masticating surface in the mouth. The heart was slightly enlarged, but was otherwise normal. Examination of the lungs gave negative results, except for a few dry, bronchial râles. A small umbilical hernia and a large reducible right scrotal hernia were noted. Rectal examination revealed only marked local tenderness. The blood pressure in millimeters of mercury was 94 systolic and 56 diastolic.

Urinalysis repeatedly gave negative results. The concentration of hemoglobin was 28 per cent; erythrocytes numbered 1,300,000 and leukocytes 4,000 in each cubic millimeter of blood. The differential count gave normal values, and blood smears gave no evidence of pernicious anemia. Aspiration of gastric content after a test meal did not reveal free hydrochloric acid. The concentration of blood urea was 15 mg., of blood sugar 73 mg. and of blood chlorides 602 mg. in each 100 c.c. The carbon dioxide combining power of the plasma was 50 volumes per cent. The value for serum protein was 4.6 gm. in each 100 c.c., of which 47 per cent was albumin. There was a proportionate reduction in the serum calcium; the reading was 7.7 mg. in each 100 c.c. Roentgenograms of the thorax gave negative results. Roentgenograms of the long bones were negative for osteoporosis. Repeated examinations of the stools were negative for parasites, pus, or blood, and an abnormal content of fat was not demonstrable by the usual tests. The Wassermann reaction of the blood repeatedly was strongly positive. A tentative diagnosis of a malfunctioning gastro-enteric stoma, with a possible gastrocolic fistula, was made and emergency intravenous injection of fluids was instituted. Transfusion of 500 c.c. of blood also was given. As the patient revived under this treatment, certain additional features were noted. He was found to be in a state of mild delirium a good deal of the time, and was extremely uncoöperative. A neurologic consultant reported the presence of extensive peripheral neuritis, with absent reflexes and reduced sensation in the lower extremities. It became apparent that the patient was suffering not only from some grave disturbance in the digestive tract, but also from latent syphilis and from a deficiency syndrome characterized by pigmentation, residual glossitis, peripheral neuritis, mild dementia, and extensive general edema of the nutritional type.

Attempts at identification of the gastro-intestinal lesion were highly unsatisfactory because of the weakened condition of the patient and his mental disturbance. Fluoroscopic examination of the stomach was attempted and it was found that some barium was passing through the pylorus while a good deal passed through a large gastro-enteric stoma into a greatly dilated jejunal loop. Because of the persistent diarrhea, repeated attempts at proctoscopic examination were made, but the patient resisted vigorously. Fluoroscopic examination of the colon seemed to be out of the question. Camphorated tincture of opium (paregoric), kaolin, a diet high in vitamins and dilute hydrochloric acid controlled the diarrhea somewhat, and at the end of three weeks in the hospital it was thought that the patient's condition was sufficiently good to attempt antisyphilitic treatment. Although it was generally agreed beforehand that the syphilis probably had no bearing on the patient's general condition, it was thought that arsenic might have a beneficial effect on the pellagrous manifestations. The patient did not make a significant response to four doses of neo-arsphenamine, although there was a slight, nonspecific, tonic effect. The neuritis remained unchanged; the pigmentation of the skin, and the eruption on the genitals were not altered in any way, and the general anasarca persisted.

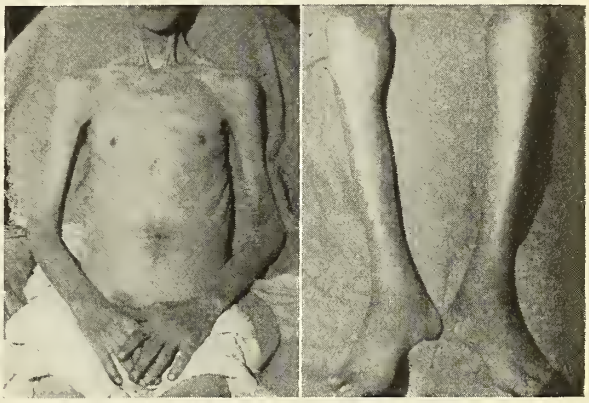

Fig. 1. The patient shortly after admission. Pigmentation of the lower extremities, emaciation, ascites, and muscular atrophy are evident.

Attempts to treat the deficiency syndrome were almost as unsuccessful. During the whole period, while the patient was in the hospital, his average daily intake of food was extremely small and he could be induced to take only very limited amounts of concentrated foods. A variety of diets was tried, but the patient's anorexia and apathy toward food persisted. His mild delirium and his lack of coöperation effectively nullified any attempts at forced feeding. The patient's last two weeks in the hospital were characterized by exacerbation of diarrhea, increased severity of the mental symptoms, and general decline in strength. The blood pressure remained extremely low, ranging from 80 to 90 systolic; the edema and ascites decreased somewhat. Solutions of acacia, of glucose, and physiologic solution of sodium chloride, given intravenously, failed to have any supportive effect. A new complaint, that of photophobia and diplopia, presented itself; it appeared to be due to convergence insufficiency more than to palsy of any single muscle. As a last resort, and because of the possibility that a gastrocolic fistula was present, sugical intervention was considered, but because of the weakness of the patient this was deferred indefinitely. At the end of seven weeks in the hospital, the patient died suddenly, and without any immediate prodromal symptoms. The suddenness of his death was similar to that which is so commonly reported in beriberi.

At necropsy, extreme emaciation, edema, and pigmentation were striking. On opening the peritoneal cavity, the omentum was found to be adherent to the scars resulting from the previous laparotomy. The abdomen contained 1,000 c.c. of cloudy fluid, and its upper portion was a dense mass of adhesions. On opening the pleural cavities, each was found to contain about 500 c.c. of cloudy fluid. The pericardial sac contained 100 c.c. of clear, straw-colored fluid. There were healed lesions of tuberculosis in the lungs and the nodes of the hilum, and there were a few subpleural, petechial hemorrhages. There was also terminal bronchopneumonia. The liver was negative to examination, except for a small hemangioma. The gallbladder contained one stone and a moderate degree of cholecystitis was present. Examination of the spleen, pancreas, suprarenal glands, kidneys, bladder, testes, thyroid gland, and thymus was essentially negative. The most significant abnormalities were confined to the digestive tract. The esophagus was normal. The stomach was contracted, especially in the prepyloric region, and on the anterior surface a stoma made at gastro-enterostomy was present and was in good condition. The mucosa of the stomach was pale and rugæ were absent. At the angle of the stomach, on the lesser curvature, the mucosa was injected and irregular; a definite scar was not present. What appeared to be the scar of a previous ulcer was noted in the duodenum. On attempting to follow the duodenum downward, occlusion was encountered about 4 cm. below the papilla of Vater (Fig. 2). At this point the lumen of the duodenum was obliterated and was replaced by a fibrous cord 4 mm. in diameter for an extent of 2.5 cm. Below this cord the lumen became normal in size, and 10 cm. farther on, in the jejunum, was the stoma of the gastro-enterostomy. The remainder of the small intestine was essentially normal. The colon, however, presented a picture of a diffuse, ulcerative type of colitis. There were many superficial ulcers with serpiginous borders, between which islands of edematous, whitish mucosa were seen. Sections of the colon revealed superficial ulceration, which in places extended to the muscularis mucosæ. These ulcers were covered with a fibrinopurulent exudate, which formed a pseudomembrane and extended over large areas of the surface (Fig. 3).

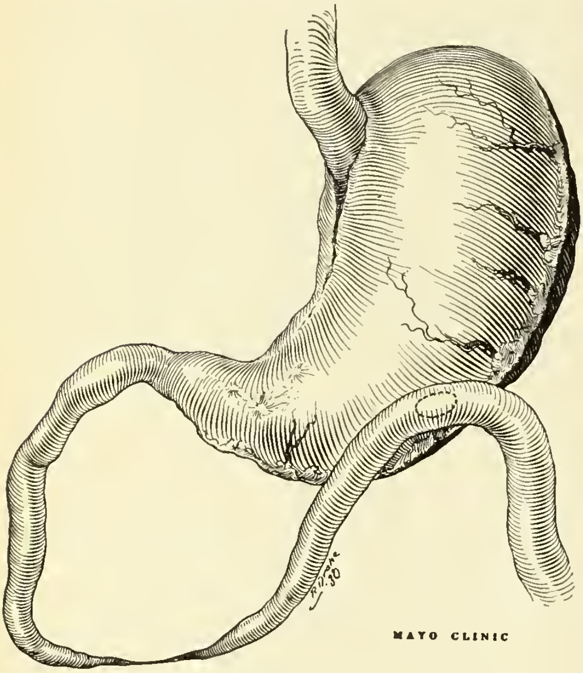

Fig. 2. The condition of the stomach and duodenum.

Because of the mental symptoms and the peripheral neuritis, a special examination of the brain and spinal cord was made. Both were normal in gross appearance, but on section definite evidences of pathologic change were encountered. In the brain, there was a section of the right superior frontal convolution which gave evidence of considerable myelin degeneration, not limited to the perivascular regions, but diffuse and extending into the radiating fibers in the cortex. A similar change, of lesser degree, was noted in the optic chiasm. The peripheral nerves, also, had undergone rather marked degenerative change, but evidence of a previous inflammatory process was not found. These degenerative processes were most marked in the nerve roots, between the spinal cord and the dorsal root ganglia. Evidences of degenerative change were also noted in the anterior roots. The left sciatic and left femoral nerves were the most involved, but all the nerves of the lower extremities had undergone definite changes. The spinal cord was not injured, except for a region of degenerative change in the posterior columns of the medulla oblongata and in certain regions of the posterior spinal cerebellar tract.

The final anatomic diagnosis was: (1) anterior gastro-enterostomy for duodenal and gastric ulcer, (2) duodenal occlusion, (3) ulcerative colitis, (4) terminal bronchopneumonia, and (5) degenerative changes of the central nervous system somewhat suggestive of those seen in beriberi.

COMMENT

The principal interest attached to this case lies in the unusual combination of symptoms of the so-called deficiency diseases. The glossitis, pigmentation, and mental disturbances suggested pellagra, whereas the peripheral neuritis, edema, ascites, and sudden death were more or less characteristic of the wet form of beriberi. The changes found at necropsy, particularly those noted in the central nervous system, were comparable to those reported in beriberi. The combination of evidences of various conditions in this case appeared to be unique and were difficult of explanation.

Although opinion is not unanimous, pellagra and beriberi both have been thought to be due to deficiency of Vitamin B. There is a general belief that Vitamin B contains more than one active principle, and Goldberger has maintained that it contains a specific factor which prevents pellagra. The dry type of beriberi probably is due to Vitamin B deficiency alone, and it has been produced experimentally in animals. The wet type probably is due to a combination of deficiency in Vitamin B and low intake or reduced assimilation of protein with subsequent reduction of the serum proteins.[2] Because of the mental disturbances of the patient whose case has been presented, it was difficult to determine exactly in what respect his diet had been deficient, but it is fairly certain that during a large portion of his illness he had taken only concentrated and artificial foods. He had largely avoided fruit and vegetables and he had taken meats only in limited quantities. He had also suffered with vomiting and diarrhea to such an extent as to interfere with the assimilation of such foods as he actually had ingested. These latter factors may explain the low level of serum protein and the edema. The other deficiency symptoms were probably due to a combination of inadequate diet, vitamin deficiency and the disturbed physiologic mechanism of the gastro-intestinal tract.

The case may be said to present an end-picture of the effect of inadequate diet on a patient whose pancreatic ferments and bile were diverted into the stomach and through it by means of gastro-enterostomy. This condition, together with the ulcerative colitis, undoubtedly produced the abdominal symptoms of which he complained. The nature and cause of the duodenal occlusion remains a mystery. It may represent the result of operative trauma or the end-stage of an obliterative inflammatory process. Pathologic examination gave no further clues as to its nature. The ulcerative colitis, which played so large a part in the production of symptoms, had some of the appearance of a terminal condition. However, bacteriologic studies were not made and it was impossible to exclude the possibility that the patient had suffered with an infection by the diplococcus of ulcerative colitis. In this connection it must be recalled that in other deficiency diseases ulcerative lesions of the bowel have been described and that in pellagra supposedly specific types of colitis have been said to exist.

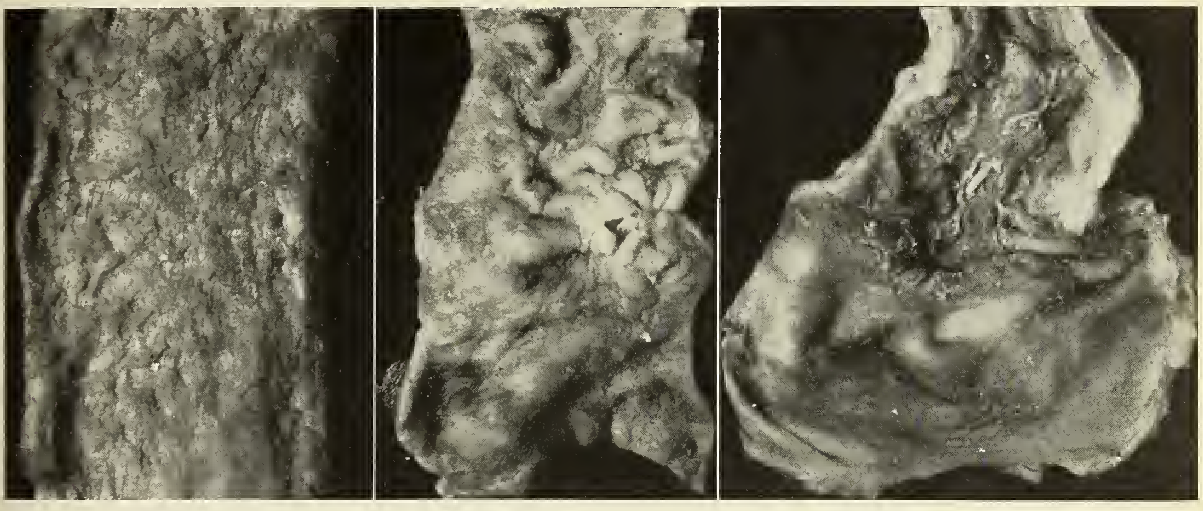

Fig. 3. Sections of the colon. There is evidence of ulcerative colitis and a pseudomembrane.

It is interesting to speculate as to the possible physiologic effect of duodenal occlusion below the papilla of Vater in the presence of gastro-enterostomy. In normal animals which have been fed on laboratory food this does not produce very significant nutritional effects, although it has been known to cause jejunal ulcers.[1] In the presence of high gastric acidity such as this patient probably had in the early stage of his disease, it is possible that the pancreatic ferments were inactivated and that this was responsible for the original diarrhea.

The manner in which disturbances of gastro-intestinal function act to produce deficiency syndromes is, of course, not entirely understood. That such syndromes do occur is a well established fact. Eusterman and O'Leary recently reported a series of cases in which pellagra was secondary to obstructive gastro-intestinal lesions, or, as in one case, to ulcerative colitis. Symptoms not unlike those of beriberi have been encountered at the clinic, usually in cases of profound nutritional disturbances of long standing. Inanition edema likewise has been observed at the clinic[7] and Landis, and Leopold, and Wolferth previously reported similar cases following gastro-intestinal disturbances. The connecting link in all of these groups of cases seems to be the combination of an inadequate diet, usually low in protein, with some gastro-intestinal lesion which interferes with the assimilation of food. What portions of these syndromes can be attributed to deficiency in Vitamin B alone is difficult to determine, but, as Minot has claimed, a multiplicity of factors may enter into the etiology of any deficiency disease of this type. It is apparent that a search for symptoms of deficiency disease should be made in any case in which, because of gastro-intestinal disease, the patient has subsisted on a restricted diet, since it is not unlikely that many mild or borderline deficiency syndromes now escape attention.

DEATH FROM EXPLOSION OF MIXTURE OF ANESTHETIC GASES

It has been two years since, at Evansville, Ind., a tank containing nitrous oxide exploded, killing an anesthetist. Last month a patient died on the operating table in Los Angeles because of the explosion of an anesthetic mixture. Yet the hazard from an explosion of anesthetics is probably less than that of fatally persistent hiccup. It has been pointed out that surgeons and anesthetists need far more to utilize means to prevent postoperative pneumonia than to worry over the hazards of explosions, except, of course, explosions due to carelessness. In the case of the Los Angeles accident, the patient was given nitrous oxide and oxygen, followed by ether. It has been pointed out repeatedly that a mixture of these gases is explosive. Explosions recorded heretofore appear to have been due to sparks from discharges of static electricity. Various committees of the American Medical Association have reported on precautions that are to be taken towards the prevention of such accidents. Jour. A. M. A., February 14, 1931, p. 530.)

KOREMLU, A DANGEROUS DEPILATORY

There has been on the market for some time a depilatory sold under the name "Koremlu Cream," marketed first under the trade name "Kora M. Lublin," more recently under the style "Koremlu, Inc.," both of New York City. According to the advertising, Koremlu is "guaranteed to devitalize superfluous hair roots on face or any part of the body." From information received it was quite apparent that Koremlu contained thallium acetate. Reports of serious effects of the use of Koremlu Cream have been reported that are typical of thallium poisoning. The A. M. A. Chemical Laboratory analyzed the preparation and concluded that it consisted essentially of an ointment containing approximately 7 per cent thallium acetate and 9.5 per cent of zinc oxide. Dr. Sabourand, who studied the effects of thallium as a depilatory, declared that any ointment containing more than 1 per cent of thallium acetate is dangerous. He cautioned that but small amounts of the one-per-cent ointment should be used at one time; no limit is given to the amount of Koremlu, which is much stronger, that should be applied. (Jour. A. M. A., February 21, 1931, p. 629.)

TWO CASES OF PELLAGRA FROM MINNESOTA

ONE WITH THE SYNDROME OF PROGRESSIVE MUSCULAR ATROPHY

HUGO O. ALTNOW, M.D.*
Minneapolis
and
HERMAN H. JENSEN, M.D.
Atwater, Minnesota

PELLAGRA was first recognized in the United States in 1902.[1] In 1914 it was estimated that there were 165,000 cases in the United States. The original pellagrous area comprised the South Atlantic states, but since its recognition, cases have been reported from practically every state in the Union. Many more cases may be recognized if it is borne in mind that any case of severe and obscure nutritional disturbance may be pellagra.

In Minnesota and the neighboring states, Head[2] reported one case from South Dakota, and O'Leary[3] of the Mayo Clinic reported thirty-four cases seen in four years, coming from the middle western and northwestern states, including three from northwestern Canada. Granger[4] in 1918 reported five cases, three of which developed in Minnesota and North Dakota. Sweitzer[5] reported seven cases in chronic alcoholics in Minnesota. Briggs and Ruhberg[6] reported two cases in alcoholics. Marsh,[7] McIntosh and Blount,[8] and Middleton,[9] reported one case each from Wisconsin. Marsten and Warren[10] noted four cases from Wisconsin, and Ely[11] recorded two cases from Iowa.

For a brief review of the etiology of pellagra, we have drawn largely upon Goldberger's excellent account[12] of the various theories concerning the origin of the disease.

Three to four centuries ago, pellagra was considered to be due to poor food. A later theory attributed the disease to the deficient and poor quality of protein in the diet of people eating corn. This idea was abandoned when pellagra was discovered in individuals whose diet contained no corn. For a long time the theory was accepted that pellagra was caused by toxic changes in the food, especially in corn, due to the action of microörganisms that were nonpathogenic to the individual, but produced a toxin. Following this, the students of the disease were divided into two groups, one of which advocated the infectious and the other the dietary theory of the origin of the disease. The former group based their contention chiefly on the following grounds: (1) abrupt appearance and extension of the disease and its limitation to the south; (2) seasonal character; (3) occurrence in the well-to-do with liberal diet, and in well nourished individuals. The second group gave as reasons for supporting the dietary theory: (1) no contraction of the disease by attendants in hospitals; (2) response of patients to proper diet; (3) complete prevention by proper diet; (4) inability to transfer disease by inoculation of well persons with secretions of diseased individuals.

In 1912, Funk stated that it was a deficiency disease: an avitaminosis. He maintained that the milling process removed an essential vitamin from the corn. He was probably the first to recognize the true character of the disease, but his premise concerning the mechanism by which it was produced was not correct.

Since the dietary has succeeded the infectious theory, the recent researches of Goldberger, Wheeler, Lillie and Rogers[13] have quite conclusively established the following facts: (1) that pellagra is due to deficiency of a vitamin called the P-P factor, which comes from the same sources as those associated with Vitamin B; (2) that this is not identical with the anti-neuritic factor of Vitamin B; (3) its chief food sources are yeast, fresh meat, butter, milk and vegetables; (4) it acts as a pellagra preventive and pellagra cure without the help of protein.

However, not all observers of this disease are ready to accept the above facts as final and for a controversial opinion the reader is referred to the discussion of Wilson.[14] Wilson does not accept the results of the animal experiments of Goldberger and his associates as far as considering "black tongue" in dogs and the dermatitis of rats brought about by a deficiency of the P-P factor in the experimental diets as being pellagra. He believes that the essential cause of pellagra is a primary or secondary deficiency in the value of the protein intake relative to individual requirement, a requirement which may be raised by various conditions. He does not consider a deficiency of the vitamin factor in itself as ever being sufficient to produce the disease.

---

*From the Department of Medicine, The Nicollet Clinic.

The following cases were first seen by one of us (H. H. J.) in a single locality in Minnesota:

Case 1.—The patient was a housewife, aged 34, who complained of generalized body pain, loss of strength and inability to move about, and swelling of the face.

Her family history was essentially negative.

The patient's appendix and an ovarian tumor were removed in 1917. In 1918 she had severe influenza and suffered from palpitation and tachycardia for the next two years. In 1919 her tonsils were removed. In March, 1927, seven teeth were extracted.

The patient was married for twelve years. Her husband was living and well and she had two children, eleven and seven years of age. One miscarriage occurred in 1918.

The present illness started in February, 1927, and was gradual in onset. The patient first noticed redness and burning of her face, and, a little later, puffiness of the face, particularly under the eyelids. Her face was swollen at the time of examination in June, although not so much as formerly, and the dermatitis was more pronounced. In March she had experienced difficulty in using her left arm and shoulder. Shortly thereafter the same difficulty appeared in the right arm. This later extended to the hands, particularly the left. In April she developed weakness in the right thigh, a little later in the left, and then in the legs. Numbness in the dorsum of the left foot was felt at different times. For two months she had increasing difficulty in swallowing, with regurgitation of liquid food. Her neck was very weak and she was unable to lift her head from the pillow. She had a rather severe, non-productive cough for two weeks. At the onset of the illness she felt hungry all of the time, but later her appetite was only fair. Since 1918 she had had attacks of epigastric pain, with diarrhea. After the onset of the present illness her bowels moved two to four times a day. She could not sleep well because of pain in the legs and nervousness.

Physical examinations showed the patient to be moderately undernourished with hard edema or swelling of the forehead, eyelids, malar regions, upper lip and ears. The swelling was greater on the right side, producing asymmetry of the face. The skin over the swollen part was rough, dry, scaly and dark from increased pigmentation. Dermatitis was present over the neck and anterior upper aspects of the thorax. In the latter location there was no pigmentation and the color of the skin was dark red. The distribution was bilateral and symmetrical, producing a "butterfly wing" appearance. The same dermatitis was present on the dorsal aspects of the fingers, hands, wrists and lower third of the forearms. Here the symmetrical distribution was even more striking than on the thorax, one side being a perfect mirror pattern of the other.

There was reddening (stomatitis) of the mucous membranes of the mouth and tongue. The muscles of the tongue showed atrophy and there was inhibition of movement of the muscles of the soft palate. Several teeth had been extracted and the remaining teeth were in good condition. The tonsils were well removed. There was a systolic murmur at the apex. Moderate fixation and pain occurred on flexion of the joints. There was general tenderness of the skeletal muscles and long bones on pressure. The temperature was 98.6, pulse 96, blood pressure 108/50. Since the patient could not stand on the scales, her height and weight were not obtained. Otherwise, the physical examination was negative.

The blood examination showed the following: hemoglobin 67; RBC 4,280,000; WBC 4,900. Differential blood count showed leukocytes 24.5; mononuclears 4; polymorphonuclears 71; eosinophiles 0; basophiles .5.

The patient was admitted to Abbott Hospital for further study. A neurological examination was made on admission by Dr. Angus W. Morrison. The face was asymmetrical, due to unequal edema. There was no apparent involvement of the seventh nerve. There was some atrophy of the muscles of the tongue, as the mucous membrane of the sides was thrown into folds. The movements of the tongue were weak. Effort produced only a very slight elevation of the palate. There was distinct atrophy of thenar and especially hypothenar groups of muscles on both sides, but it was much more marked on the left. There was a more definite hollowing of the first interosseous space, especially on the left side, and of the other interosseous spaces than is usual. All motions could be performed, but there was marked weakness in gripping, abduction and adduction of the fingers and particularly in approximating the thumb to the little finger, more marked on the left than on the right side. There was loss of tone of all muscles of the extremities, with atrophy of flexor groups in the forearms. Movements of the elbows and shoulders could be carried out, but were weak, and there was some limitation in action, due to what appeared to be shortness in the biceps tendon and limitation in adduction of the shoulder joint, particularly on the left side. There was no marked atrophy of supra- and infra-spinatus muscles. The neck muscles were extremely weak, the head falling in one direction or another. All movements of the lower extremities were weak and there was some atrophy of external peroneal groups. All movements could be performed. The biceps and triceps were barely present and equal. Knee jerks were not obtained. The left ankle jerk was greater than the right. Abdominal reflexes were all present, but the right tired more easily than the left. Both lowers disappeared on repeated tests. Sensory examination was negative. Deep sensibility and joint sensation were normal. The tentative diagnosis was progressive muscular atrophy with bulbar palsy. On June 12, 1927, the patient was seen by a consultant in dermatology, Dr. H. E. Michelson. In his diagnosis he considered the following possibilities: (1) pellagra;

(2) disseminated lupus erythematosis; (3) edematous stage of scleroderma. Absence of temperature and acute onset completely ruled out disseminated lupus erythematosus. The edematous stage of scleroderma was rejected because of the color of the involved area and the non-resistant character of the edema. The dermatitis, stomatitis, apathetic state and intestinal symptoms all pointed to pellagra.

On June 7, the urine reaction was alkaline, with specific gravity 1.019, no albumin or sugar, sediment, 10-15 pus cells per H. P. F. and no casts.

One June 9, the sugar tolerance with 100 G. glucose was fasting sugar 100 mg. per 100 c.c. the first hour and 134 mg. per 100 c.c. the second. An X-ray examination of the long bones and joints showed decalcification. There was no evidence or arthritis. The changes were apparently due to disuse atrophy.

An examination of the stool on June 10 showed it to have an offensive odor with alkaline reaction, undigested food, and no ova or parasites.

On June 11 the blood examination showed WBC 7,100, with a differential count of 25 leukocytes, 68.5 polymorphonuclears, 7 mononuclears, no eosinophiles and 0.5 basophiles.

The patient remained in the hospital one week. She was placed on a high protein diet with an abundance of green and cooked vegetables. Her afternoon temperature varied between 99.2 and 99.8, and her pulse rate from 100 to 104.

Several months later she entered a sanitarium, where she died on November 11, 1927, about six months after she first came under our observation.

Autopsy by Dr. E. T. Bell was limited to abdominal incision. The body weight was estimated at 99 pounds. There was brownish pigmentation of the face and neck, with a triangular area down on the thorax. There was no pigmentation of the arms or legs. The organs of the chest and abdomen were essentially normal, except for terminal bronchopenumonia of the right lung. His diagnosis was: (1) pellagra; clinical; (2) terminal broncho-pneumonia.

Because of the advanced muscular atrophy and the helplessness of the patient, the first clinical impression did not particularly suggest pellagra, but the stomatitis, gastro-intestinal symptoms, symmetrical dermatitis and central nervous system degeneration could be explained only on this basis. We had come to this conclusion, independently, although at the time we were not familiar with such marked central nervous system degeneration occurring in the course of pellagra. We have not found this feature of progressive muscular atrophy with pellagra reported in the literature. Spastic paraplegia, ataxia and marked muscular weakness have been described.

Wood[14] states that one of his fatal cases presented a classical picture of acute Landry's paralysis and cites Kinnear Wilson as mentioning neurological findings in pellagra having a marked resemblance to subacute combined degeneration. Wood also states that in some cases the neurological aspect is typical of subacute combined degeneration. He further cites Neusser as describing a case of amyotrophic lateral sclerosis occurring with pellagra and the inference that it was of pellagrous origin, "but such would hardly be accepted without more evidence."

Roberts[15] points out that spinal cord lesions fall into three groups: (1) probable pyramidal tract degeneration. He quotes other students of the disease as stating that muscular atrophy of some degree occurs in approximately 50 to 60 per cent of the cases. This involves extensor more than flexor groups, often producing contractures.

The case of Middleton[9] had fibrillary tremors and speech and deglutition difficulty, suggesting anterior horn and bulbar involvement.

Aside from this, Cuno[16] reports the case of two brothers, fourteen and twelve and a half years of age, in whom progressive muscular atrophy was present. Both showed marked improvement and one almost complete rehabilitation after being fed yeast, codliver oil and a vitamin-rich diet. He regarded a possible avitaminosis as the cause of the nervous lesions.

In investigating more closely the dietary habits of the patient above reported, it was found that during the year prior to the onset of the disease the patient had lived on a farm in South Dakota; there had been a complete crop and garden failure, and the patient's diet had consisted largely of potatoes, bread, eggs, and pork with only a little milk and very few vegetables.

Case 2.—This patient was a farmer, sixty-two years of age.

Since 1916 he had had three attacks of manic-depressive psychosis. The last one was in 1923 and was the most marked, lasting for about six months.

The patient was admitted to Abbott Hospital September 15, 1928, complaining of weakness, diarrhea, loss of weight, anorexia and insomnia. His brother-in-law stated that the patient had not been feeling well since April of that year. About the first of July he developed loss of appetite, sleeplessness and restlessness. He began to show definite evidence of a psychosis and mental depression. About one week later he developed diarrhea, which was present to some extent in the community. Vomiting began about the first of September and the patient took nothing to eat except a little orange juice until he entered the hospital. The vomitus was green at first, and later brown and foul smelling. The patient stated that his stools had been dark and tarry and that he had lost about twenty-five pounds.

Physical examination showed the patient to be greatly emaciated and dehydrated, and somewhat confused and disoriented. There was hyperemia of the hard and soft palate. The tongue was smooth and red, with ridging at the center and lateral furrowing. The pharynx was reddened and adhering to it was a stringy, white exudate, similar to an exudate appearing on the palate.

The lungs were hyperresonant, with dry râles under each clavicle and sibilant râles at both bases in the mid-axillary line. The heart tones were poor, with some irregularity in rhythm. The abdomen was scaphoid and tender. No mass was felt and there were no enlarged lymph glands or rectal shelf.

There was a brown, spotted pigmentation, similar to freckling, on the dorsum of both forearms, extending to the elbow. On the back of both hands there was an irregular area about 10x10 cm. which was smooth and pink and seemed to be due to peeling of the brown skin. The distribution and shape on the hands was symmetrical. There was pigmentation encircling the neck, similar to that on the forearms. The skin of the nose was rough, pigmented and slightly red at the tip. The skin over the elbows and knees was also rough and pigmented.

A Van Slyke test on the day of admission registered 48 per cent, and a non-protein-nitrogen test 54.5 per cent.

During the first thirty-six hours after admission the patient was given 4,000 c.c. of 5 per cent glucose and the vomiting stopped. A tentative diagnosis of pellagra was made on admission, and as soon as the vomiting had stopped, raw beef juice, yeast and orange juice were given.

On September 17, a gastro-intestinal examination showed no free hydrochloric acid in the stomach contents. On fluoroscopic examination the pyloric end of the stomach did not fill. Six hours later the same findings were present and the cardiac end of the stomach was still filled. There appeared to be a trickle of barium to the pylorus.

The patient took food well for two days, then he resumed vomiting and his mental condition became so much worse that it was impossible to feed him. On each succeeding day he showed more exhaustion and on the eighth day he developed a pulmonary edema and died.

An autopsy was performed by Dr. J. S. Harter of the Department of Pathology, University of Minnesota. The essential findings were as follows: Pigmentation was present as described above. The right pleural cavity contained 200 c.c. of straw-colored fluid and the pericardial sac contained 250 c.c. The lower lobes of both lungs were edematous and congested on section. The stomach and gastro-intestinal tract were normal except for three diverticulæ in the upper portion of the jejunum. The pathological diagnosis was pellagra.

When this patient was first seen by one of us (H. H. J.), he was thought to be suffering from a carcinoma of the stomach. On admission to the hospital the two patches of dermatitis were noticed on the back of the hands. On inquiry, it was learned that this dermatitis had recurred for three previous summers. This established the photo-sensitive character of the condition and suggested the possibility of pellagra. The gastro-intestinal and X-ray findings appeared to confirm the diagnosis of a co-existing carcinoma of the stomach. Opposed to the latter diagnosis were the absence of pain and the fact that no palpable tumor could be felt in the abdomen, where it should be almost visible. Because of the patient's weakened physical condition, the fluoroscopic examination was difficult and unsatisfactory. Plates were not made. In view of the postmortem findings, it must be concluded that the lack of filling of the distal half of the stomach was due to pressure of the spine.

The dietary habits of this patient were excellent and he was not an alcoholic. He must be considered as one of the rather infrequent cases of pellagra designated as the idiopathic type, whose eating habits show no evidence of gross dietary deficiency. His last attack of manic-depressive psychosis with anorexia and diminished food intake was no doubt a precipitating factor in bringing on the terminal stage of the disease, although it was not entirely responsible, since his history reveals the fact that the cutaneous manifestation was present for at least three years before the terminal illness.

ROOMS OF RAMSEY

A ride in a swift green elevator brought the Hennepin County visitor to the top floor of the new Lowry Medical Arts Building in Saint Paul, where the Ramsey County Society held open house in their new rooms February 27, 1931. Creamy plaster walls and walnut woodwork give a sense of restful dignity. A delightful antique table in the periodical room is surrounded by chairs covered with woven straps of pigskin. Cretonne window drapes, gay but not too gay, and a perfectly luscious armchair conspire effectively to make the reader feel at home. Soft oriental rugs seem to be everywhere. The walnut Windsor chairs in the main reading room are of the heaviest construction so that even the most corpulent of the local profession can sit in one for hours at a time without fear of collapse. The library stacks are arranged on two floors, and there are study cubicles under the windows with walls so high that full privacy is assured the occupant unless he stands up and cranes his neck out.

The auditorium has rough, creamy plaster walls with pilasters of ivory, and rich blue-green window draperies. The lighting fixtures, specially designed, are modernistic in effect, but cunningly escape boldness. The softly frosted glass eliminates glare without casting shadows and gives a sense of friendly brightness to the room. Handsome display cases are built into the wall of the corridor and of the auditorium for the collection of old books and instruments which has been arranged chiefly by Dr. John Armstrong. One case contains a remarkable array of nursing bottles, loaned by Dr. Robert Rosenthal, including a pottery one from Rome, antique china, glass and silver ones from Europe and Colonial America. Of interest is a flat silver nipple which can be plugged into any cork. Thus any bottle can be gotten up to tempt the infant appetite, but scarcely to deceive it. Old books, rare books, were in every case. Especially noteworthy was a collection of book treasures on ophthalmological subjects loaned by Dr. Frank E. Burch.

Dr. O. W. Holcomb, the newly elected president, sat at the table on the platform, flanked by Drs. Justus Ohage, Wm. Davis, H. Longstreet Taylor, Jennette McLaren and J. C. Markoe, early members of the Ramsey County Society. Dr. John Armstrong sketched the beginnings of the Society and called attention to the bronze name plates of the founders which had been placed in the entrance lobby. The meeting place of the first eight members in 1870, in a small dark room over a beer saloon, was contrasted with the present quarters, and the important steps taken by the Society in the intervening years were traced. Dr. H. Longstreet Taylor outlined the beginnings of the library when the members of the committee spent Saturday afternoons collecting books and periodicals from the homes of the local doctors, aided and abetted by the good housekeepers who presided there. A week-end horse and buggy trip to the southern part of the state yielded a valuable collection of library material, although it and the committee members were nearly lost in the mud and rain of the unfenced roads between the infrequent farm houses on the night trip homeward. The late Dr. Edouard Boeckmann, whose method of making catgut, bequeathed to the Society, has so generously provided for its financial needs, was cited for his loyalty, enthusiasm and vision which, manifested throughout his lifetime, still continues to influence the progress of the Society. Dr. John Armstrong and Dr. Frank Burch were characterized as the latter-day saints of the library because of their devotion to its development.

The guest speaker of the evening, Dr. Alfred Brown, Omaha, associate professor of surgery, University of Nebraska, delivered a fluent and scholarly address on the development of surgery after the crusades, emphasizing particularly the influence of the medicine which had been brought to Europe from the Orient, and its spread from the center at Salerno.

The attractive buffet supper which was served in the auditorium at the close of the meeting emphasized the feeling of hospitality and friendliness which was evident throughout the evening. Ramsey County Society seemed to say, "This is our medical home, and we are glad to have you enjoy it with us."

O. S. H.

Who would exchange walnut woodwork with "creamy plaster" (and frosted glass) for the oak tables, sawdust, and stench of lager of olden days?—Ed.

(*Bull. Hennepin County Medical Society,* Mar. 10, 1931.)

COSAS MEDICAS FILIPINAS
(Philippine Medical Affairs)

Ralph T. Edwards, M.D.
Elysian, Minnesota

IN the Philippine Islands, situated in the oriental tropics, most oriental and tropical diseases prevail. However, there are two notable exceptions. Yellow fever has never been found, though the specific mosquito carrier abounds. Infection from South and Central America has been escaped probably because of the long time required for sailing ships to span the Pacific over the ordinary trade routes. In modern times quarantine regulations prove an effective barrier. Nor have there been any cases of human trypanosomiasis or true sleeping sickness, but this is more easily explained as the insect carrier, the tsetse fly, does not exist in the Philippines. However, surra (enzoötic trypanosomiasis) is common, though it has not been known to attack man.

It is not uncommon to wade through a foot of water to reach the Manila streetcars, such rains assisting greatly in the sanitation of ground high enough for drainage, but much of the six foot annual rainfall comes in daily showers through the wet season, just enough to keep the lowlands wet and steamy, an ideal incubation for filth diseases.

As here, so there, in the dry season dust-borne diseases prevail. The great amount of sunshine and the beautifully ventilated houses cut down the rate for tuberculosis, pneumonia, scarlet fever and diphtheria, though smallpox is especially severe.

Most of the country is low enough to have a tropical climate, but to the north of Manila is Baguio, the health capital of the Islands, which, on account of its altitude, is almost temperate in climate.

As in the southern part of this country, and in most of the Orient, so in the Philippines, agriculture plays an important part in health conditions. Rice is the chief cereal food. In fact, no other cereal could be raised in sufficient amount to take its place. Rice is planted, and for weeks grows in standing water, with accompanying mosquito and malaria breeding. One may stand on a hillside and see both sides of the valley terraced into little level fields with rice growing in standing water, then turn and see Manila cut up by canals and the river, a beautiful sight. However, were it not for the fact that everyone sleeps under a mosquito net, the malaria deaths would be appalling. One must acquire considerable skill to get into bed without allowing mosquitos to enter the canopy at the same time. I have seen as many as 275 mosquitos on one side of the canopy waiting for a victim. In addition to serving as breeding places for mosquitos these rice fields also harbor the hosts of at least two kinds of flukes.

Carabaos, Hindu humped cattle, and native cattle stand surra or enzoötic trypanosomiasis very well, but do not give much milk. Western cattle are very susceptible, thus making dairying hazardous and fresh milk so dear that few natives can afford it. The milk of the water buffalo is used to some extent by the natives for infant feeding, but is so scant and highly concentrated as to be of little help. These primary supplies are supplemented by many brands of condensed and some of sterilized milk, most of it coming from Holland. Nevertheless, the native family, living on from fifty cents to one dollar per day, and improvident in the extreme, often suffer from vitamin insufficiency, and the baby, least able to tell its troubles, suffers first.

Beri-beri, a B avitaminosis, was formerly rampant and half the babies died the first year. Science has not only proved, by much experimental and clinical evidence, that beri-beri is an avitaminosis, but now has a definite specific cure in tique-tique (tiki-tiki), an extract of rice husk, now manufactured extensively in Manila for the prevention and cure of this plague of the Orient (Fig. 1).

Sunshine, with abundance of fruits and vegetables, acts as a preventative of rickets, so that in a recent year, among over 35,000 admissions to the Philippine General Hospital, there was not a single case of rickets and but few of scurvy, mostly from the shipping trade, but there were ninety-nine admissions for beri-beri.

At the time of the American occupation, the native city of Manila was in a swamp, especially during the rainy season, though the walled city was dry, as were also some of the suburbs.

The accompanying cut of a typical native outhouse (Fig. 2) shows how, in the wet season, any food-borne pestilence would spread. For the same reason tinea soleum throve whether the season were wet or dry, as pigs had free access to the droppings and were not at all backward about answering the call to lunch. Under American rule this has been done away with in Manila, and will, in time, be changed throughout the Islands, though under Spanish rule "It is the custom" made it perfectly right.

During the rainy season mosquitos are a veritable plague, with accompanying malaria, dengue or break-bone fever, and other mosquito-borne diseases, yet the native took no precautions except that the whole family slept under a common mosquito net, putting it away in the morning to make room for the daytime use of the house.

To raise Manila out of the mud is no small task, but it is being done. There is a saying that "The Constitution follows the Flag," but perhaps we had better say that good roads follow, because travel and commerce must have roads. The streets were filled with rock, with a crushed rock surfacing. Philippine rock being soft, this surfacing soon becomes mud, is scraped off and used to fill low places in the city while trainload after trainload of crushed rock is added to the streets.

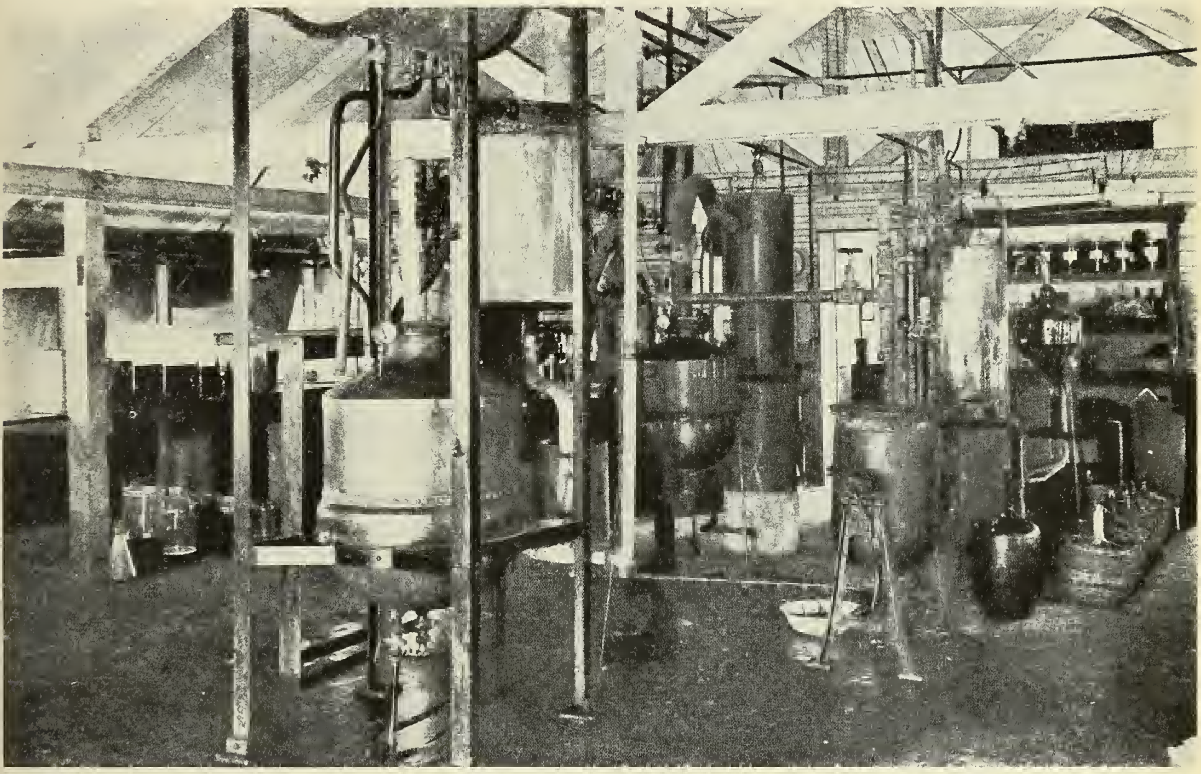

Fig. 1. Tikitiki-extraction plant, Manila.

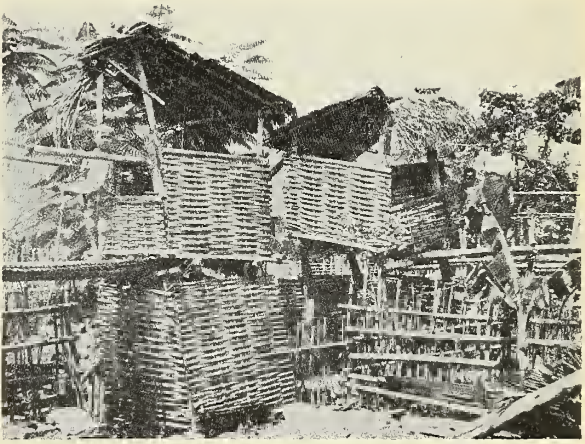

Fig. 2. Typical outhouse.

Sea commerce, like that on land, also demands better facilities. Formerly ocean-going ships were compelled to stop out in the bay and transship their cargoes to casgoes or barges of light draft which could go up the river to the customs house. A great sea wall was built a mile or so out in the bay with a gap for a harbor entrance. A square mile of the bay next to the city was enclosed in a wall, and the centrifugal dredge "Manila" filled that square mile with mud from the harbor, and now passengers walk directly onto the decks of ocean-going steamers. Even this did not make enough harbor, so another 160 acres was walled and filled with harbor dredgings and possibly more fills will follow. On the first square mile are government buildings fitting for the chief seaport of the Islands; on the second fill are various semi-public enterprises: the Manila Hotel, the Elks Club, the Army and Navy Club, the University Club, etc., so that, instead of approaching low dingy mud flats, one now meets "modern Manila."

Low spots in the city were too far away to be filled from the bay, so, when these harbor fills were completed, the dredge improved the river and threw the dredgings into the moat about the Spanish walled city and into other low districts near the river. Then much of these dredgings was hauled to low places too far for the dredge to throw and through the middle of this filled district runs Taft Avenue, flanked by the Y. M. C. A., the Columbia Club, the University of the Philippines, the Philippines General Hospital, and the Bureau of Science, signs of a modern healthful city, and Manila is coming up out of the mud.

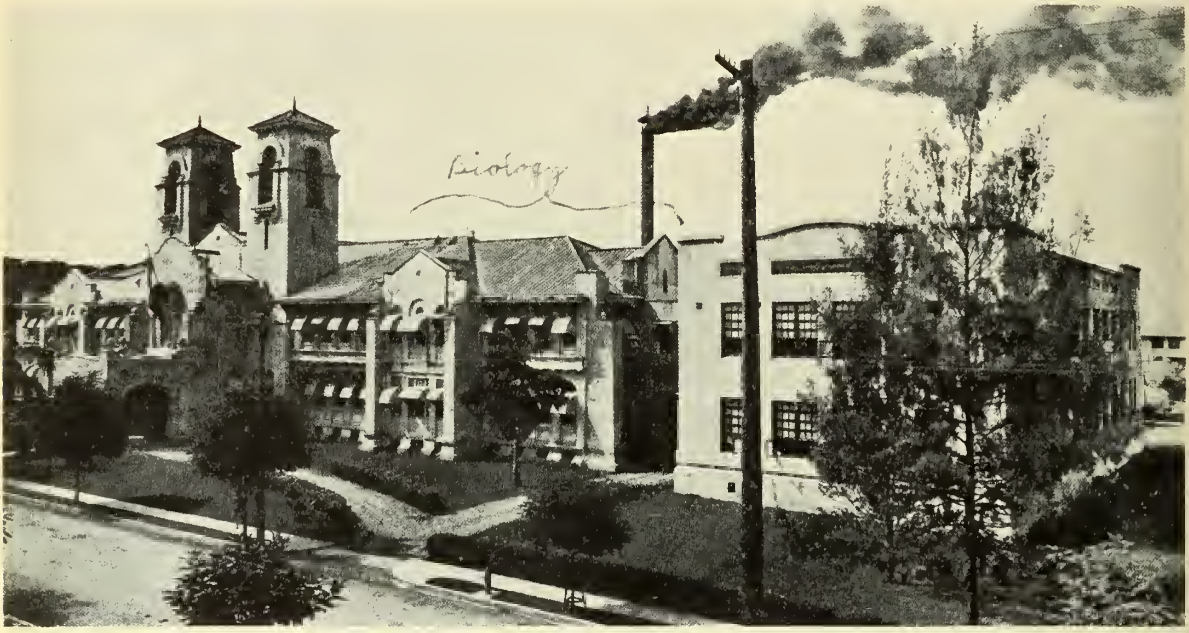

Fig. 3. Main building and east wing, Bureau of Science, Manila.

As there are some fifty or more dialects spoken in the Islands, and as education had up to the time of occupation been only in reach of the "classes," America began the task of educating the "masses." Spanish was the official language of the country, but spoken only by those who could afford school. Schools were established wherever possible with American teachers, teaching only in English, to make a common language. In a few years young Filipinos began teaching under American supervision and more schools were established. Now elementary grammar and high schools lead to normal school or college and the University according to the aspiration of the student. In 1927 there were over a million enrolled in the elementary schools and over 6,000 in the University. This does not equal the present showing in Minnesota, but it is not probable that many states in the Union have made a better showing even thirty years after admission to statehood. Educationally also it is evident that Manila is coming up out of the mud, with higher intelligence making for better health.

In addition to these external means of improving the city's health, there are two bands of men in charge of making the city, and in fact the whole insular group, healthful.

The Bureau of Health works much as a state board of health, their work modified by peculiarities of place and people.

The Biological Department of the Bureau of Science consisted, in 1906, of eight Americans and ten or twelve Filipinos whose duty it was to study plants, animals and men, dead or alive, with the aim of advancing the science of health, more especially of man, but also of plants and animals. Figure 3 shows the main building of the Bureau of Science, much as it is today, where the medical staff worked, and many earnest hours of work were put in on health problems in that quarter of the old building.

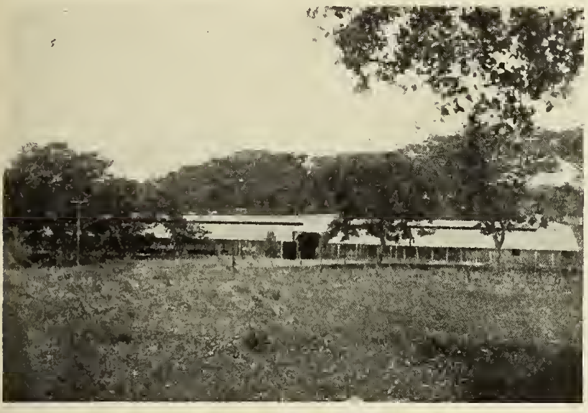

Fig. 4. The horse stables at Alabang.

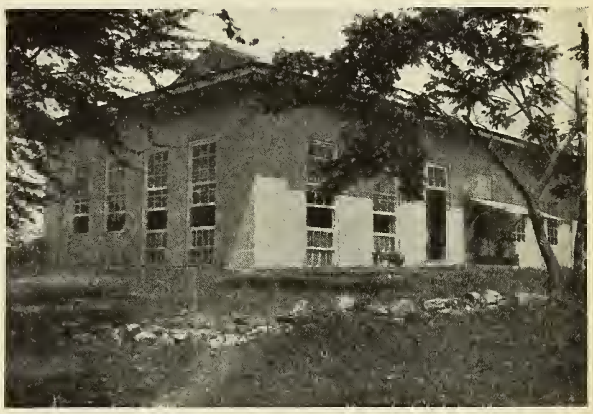

Fig. 5. The main laboratory building at Alabang.

Formerly, a large building at the back of this housed the experimental animals, from white mice and guinea pigs to horses and cattle, with an occasional python and cobra, but now there is a large plant at Alabang, a suburb of Manila, where much of the serum work is done. (Fig. 4.)

Dr. Victor G. Heiser, for many years Director of Health in the Philippine Islands, stated, in 1922, that before American occupation the annual death toll from smallpox in the provinces immediately around Manila alone was 40,000, and in Manila, 6,000. Now it is not uncommon to go a year without a smallpox death in Manila. The extreme heat makes the keeping of smallpox vaccine without ice a matter of but a few days or weeks at best. Therefore compulsory vaccination is difficult, except near Manila. About 1920 there was a campaign to abolish compulsory vaccination in the provinces on the ground of its being a failure, but investigation showed that the vaccine sent municipal officers was thrown unused into the waste basket, and more successful vaccinations were reported than there were people in the municipality. After this the Bureau of Health again sent its own men to do the vaccinating, and the death rate for smallpox again dropped; seven to twelve deaths per year being considered about normal for the provinces.

Although there is little diphtheria in the Philippines, an adequate supply of antitoxin is made by the Bureau of Science.

Other curative sera are made and kept for local needs, thousands of doses of Shiga dysentery serum being used each year.

No consideration of the medical situation would be complete without a word about leprosy, since about two out of each thousand are lepers.

Twenty to twenty-five years ago, at the beginning of effective segregation of lepers, 200 to 300 examinations were made annually by the Bureau of Science, but this work has been so increased that, in 1926, there were 6,394 in segregation. This of course does not include many of the very early cases, because leprosy is generally concealed as long as possible, though in late years more and more early cases apply for treatment.

Formerly leprosy was a hopeless disease, but in 1929, 553 cases were released on parole as arrested or cured, making a total released since 1922 of 2,013.

One-third of the appropriation for health service is allotted to segregation and treatment of leprosy. In addition there is the Leonard Wood Memorial, $342,500, allotted to three stations. John D. Rockefeller, Jr., has given $100,000 and the Eversley Childs gift is said to be the largest of all, but how large I have not been able to learn. The campaign began with a segregation station at Manila called San Lazaro, to be followed by the leper colony on the Island of Couillon, where 6,000 lepers are accommodated. Now the plan is to have stations in the various provinces much as we do our tuberculosis sanatoria. Figure 6 shows a plant for making ethyl ester of chaulmoogra oil, Manila.

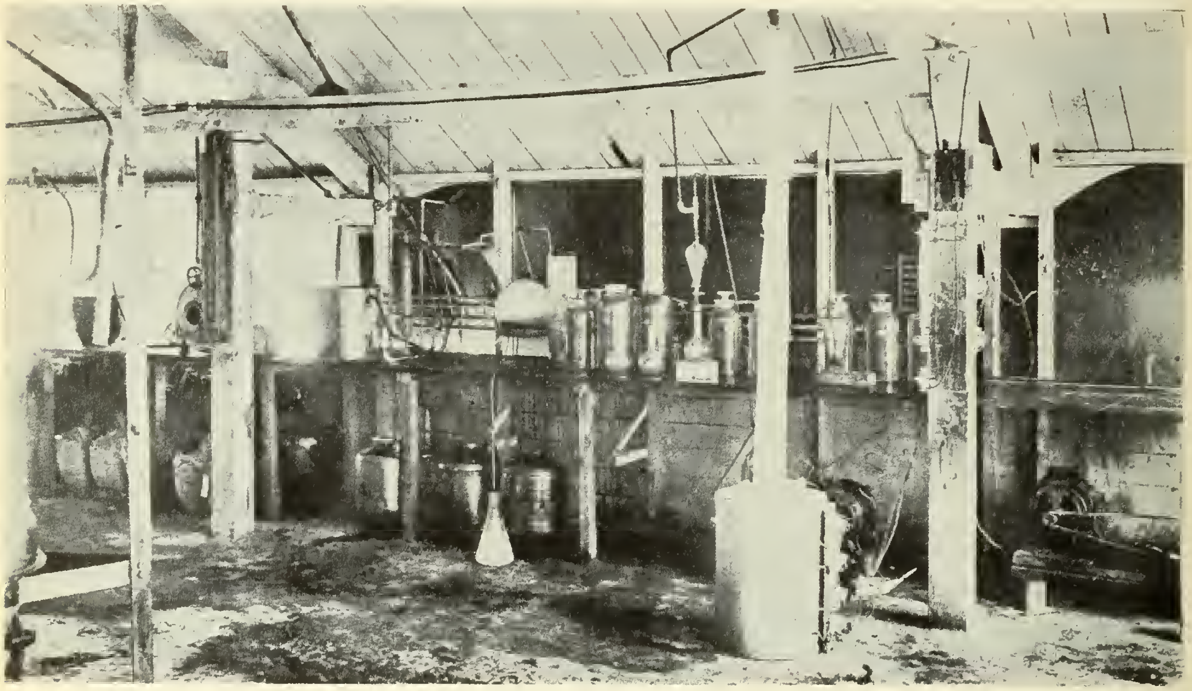

Fig. 6. Plant for making ethyl ester of chaulmoogra oil, Manila.

The arrested or cured lepers are becoming more and more of a problem in themselves, since the Filipinos are becoming leprosy-conscious, and most of the parolled cases return to Couillon, the leper colony, outcasts unable to return to their former places in society, or even to make a living away from the colony. So there is a need for the establishment of a colony for parolled cases. A certain number do relapse and must return to the treatment stations for more care.

Yaws, a disease somewhat resembling syphilis and like syphilis cured by intramuscular or intravenous arsenic, is fairly common.

Elephantiasis is hard to eradicate, because the filaria larva appears in the general circulation chiefly during the night, the regular feeding time of the carrier mosquito.

Madura foot, superficially resembling elephantiasis, but caused by a mycetozoa and akin to actinomycosis or lumpy jaw of cattle, is also hard to eradicate because of the barefoot habit of the common people.

For many years Santo Tomas University and Hospital had been graduating a few poorly trained men who practiced in and about Manila. Under American tutelage, laws have been passed making medical practice requirements of a very high order. In 1906 the medical department of the University of the Philippines was established, with men from the Bureau of Science and other men from the best American medical schools composing the faculty. Now both the faculty and the staff of the Bureau of Science are almost entirely Filipino, graduated from their own national school.

When America began the task of making Manila and the whole archipelago a more healthful place, military hospitals and military officers were utilized to enforce regulations. Later the Civil Hospital for government employees was established in a big rambling house, with two American physicians and a few American nurses in charge. Then the General Hospital was established under American management. Now there are over 90 registered hospitals in various parts of the archipelago with a capacity of over 8,000 beds.

We must not forget that, while this progress has been made, there are thousands of square miles where as yet no civilized man has set foot, with which no news is interchanged with the rest of the world.

A very marked improvement in health has been accomplished during the thirty years of American occupation, but any marked further advance must accompany improvement in economic conditions. There are now several thousand people for each registered physician, but any further supply must be native, for a foreigner will make more money elsewhere. It is almost axiomatic that a house visit should cost somewhere near the daily wage of a laborer. Twenty years ago the daily wage of a laborer in Manila was fifty cents or less, and native physicians were charging the price of two days' work or one dollar per visit, which naturally put the service of even the native physician out of the reach of the laborer. Present wages and fees I do not know, but I am sure that with the inadequate supply the laborer and others of the lower classes receive but little attention. A few American and other foreign physicians still remain to minister to the foreign population and the more well-to-do, but the majority of the natives must depend on the present inadequate supply, which, keeping pace with the advancement of the economic state, will possibly be adequate in another fifty years.

In 1906-1907 a special effort was made to improve the health of the prison population, isolating communicable diseases and, so far as possible, ridding all the inmates of parasites. At the beginning of the effort the city death rate and that of the prison was the same in spite of the crowded condition of the prison—forty-seven per thousand. After a year of effort the prison rate was cut to seventeen per thousand, showing some of the possibilities for improvement in tropical death rates.

At the time of American occupation, the infant death rate was 500 in Manila, where the people were most under the influence of western medicine, and the rate in the provinces was not known. Now, by education and sanitary laws the rate has been cut to 240. The rate is still too high but cannot be greatly improved till economic conditions permit better care of mothers and babies.

At first the general death rate was 150, rising in epidemic times even up to 300. After thirty years of education and effort it has been reduced to about twenty-seven, while at the same time the rate among the American residents is but nine. This comparison is not entirely accurate, for none in poor health is likely to seek residence in the tropics, and many who find themselves in serious ill-health return to America.

It will be seen that educationally as well as physically Manila is coming up out of the mud. With the accompanying improvement in the islands economically, hygienic conditions will also improve.

Acknowledgment is made to the Bureau of Science for the illustrations accompanying this article, which have been reproduced from various Bureau Reports.

CASE REPORTS

CARCINOMA OF THE PANCREAS WITH ESOPHAGEAL OBSTRUCTION FROM METASTASIS TO THE LYMPH NODES OF THE MEDIASTINUM*

REPORT OF CASE

Porter P. Vinson, M.D.
Division of Medicine, The Mayo Clinic,
and
James M. Marshall, M.D.
Fellow in Surgery, The Mayo Foundation,
Rochester, Minnesota

Obstruction to the passage of food through the esophagus is almost always the result of an intra-esophageal lesion. The elasticity and mobility of the esophagus is so great that lateral displacement of the organ does not interfere with swallowing and it is seldom that a tumor of any type will completely surround the tube and produce obstruction to the passage of food. The following case is presented because of the rarity of esophageal obstruction from extra-esophageal lesions.

REPORT OF CASE

A woman, aged fifty-nine years, was admitted to the clinic April 17, 1930. For six months prior to admission she had suffered from indefinite dyspepsia, with gas on the stomach, associated with much upper abdominal fullness. A dull, epigastric pain then gradually developed; it came on irregularly after eating, and lasted an hour or two, regardless of measures used for relief. In the four weeks immediately before the patient came to the clinic, she had had a constant feeling of nausea and epigastric fullness, but no vomiting. Weakness had been rapidly progressive and she had lost about 15 pounds in weight.

On examination, the patient was found to be very weak and undernourished. There was moderate rigidity of the muscles over the epigastrium, but a tumor could not be palpated. The concentration of hemoglobin was 62 per cent; erythrocytes numbered 4,400,000 and leukocytes 9,300 in each cubic millimeter of blood. The urine was normal. Analysis of gastric content revealed free hydrochloric acid to be 26 and total acidity 38. Material obtained by lavage of the stomach measured 350 c.c. and contained particles of food eaten the night before. Roentgenologic studies of the gastro-intestinal tract revealed obstruction of the duodenum about 10 cm. distal to the pylorus.

Abdominal exploration was performed by Judd, April 18, 1930. The pancreas was found to be very hard throughout. There seemed to be ulceration of the duodenum and proximal to this region of ulceration the duodenum was tremendously dilated. At operation, it could not be decided whether the condition was one of carcinoma of the pancreas or whether a large inflammatory duodenal ulcer, with secondary pancreatitis, was present. As the chief symptom to be relieved was the duodenal obstruction, posterior gastro-enterostomy was performed. There was no evidence of obstruction of the bile ducts.

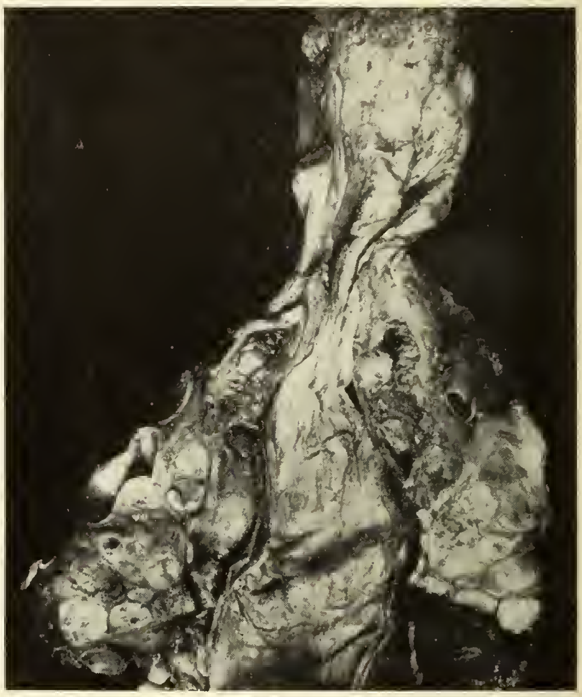

Fig. 1. Metastatic involvement of mediastinal lymph nodes, with consequent almost complete occlusion of the esophagus.

Convalescence was uneventful until about the seventeenth day after operation, when jaundice developed. The following day, the concentration of serum bilirubin was found to be 6.0 gm. in each 100 c.c. of blood and the van den Bergh reaction was direct. The jaundice progressed rapidly and obstruction to the flow of bile became complete. About this time, examination of material which drained from the duodenum failed to reveal bile. Operation was advised but the patient refused. Weakness progressed, the jaundice deepened, and finally, after twenty-seven days of complete biliary obstruction, she consented to another exploration.

June 2, 1930, Judd performed cholecystgastrostomy for obstructive jaundice due to obstruction of the common bile duct by tumor of the head of the pancreas. Immediately after the operation the jaundice became less marked, and by the tenth day had disappeared. However, the patient's strength gradually failed, and she died nineteen days after the second operation, from weakness and inanition. A week or more before her death she complained of difficulty in swallowing, and also of difficulty in vomiting. The general condition of the patient did not permit antemortem investigation of the esophagus.

---

*Submitted for publication August 1, 1930.

Necropsy revealed an extensive malignant growth of the pancreas, with extension to the wall of the duodenum, producing duodenal obstruction, and also occluding the lower end of the common bile duct. There was extensive metastasis to the mediastinal lymph nodes, two of which almost completely occluded the esophagus (Fig. 1). There was extensive metastasis to both lungs.

IMPALEMENT OF THE RECTUM

REPORT OF CASE

Harold E. Hullsiek, M.D., F.A.C.S.*
Saint Paul

Impalement wounds of the rectum are among the most serious of the accidents of civil life. They are most frequently met with in agricultural districts, where they occur usually as a result of individuals sliding or jumping from hay-mows or wagons and becoming impaled upon pitch-forks, hoes, or similar implements. Males make up the majority of the victims. In Heath's series of eighty-three cases, seventy were males. In forty-six instances the smooth handles of pitchforks, hoes, brooms, etc., were responsible for one-half.

Anatomic configuration influences the course of the foreign body, and the weight of the person together with the height from which he falls are also important factors. The converging aspect of the buttocks deflects the impaling object toward the ischio-rectal space, while the bony framework guides it thereafter. The object may pass through the anal orifice without injury to it, it may perforate the perineum, or it may penetrate the tissues lateral to the anus. Once inside, it is not uncommon for it to become impacted against the sacrum, either the sacral promontory or the foramina, or it may travel on upward. The rectum is the most frequently involved organ, and next in order is an accompanying wound of the bladder. Septic peritonitis resulting from perforation of the abdominal cavity is a frequent and to-be-dreaded complication.

It is remarkable to note what appalling injuries of this type may occur and still be followed by recovery. Woodbury reports the case of a girl of eighteen years of age, who fell eight feet onto a stake three inches in diameter, which passed twenty-seven inches and emerged at the left side of the breast, fracturing three ribs on the way. The girl was back in school in six weeks. It is interesting to speculate as to the course of the perforating body in this case.

On the other hand Heath's patient fell only four inches onto the handle of a hammer and died in a few hours. At autopsy a fragment of trousers was found in the abdominal cavity together with small masses of feces.

In Van Hook's series the mortality was 35.5 per cent, but of the thirty cases having extra-peritoneal injuries only, all recovered. Those having peritoneal involvement had a mortality of 71.4 per cent.

Careful cleansing, removal of any foreign material, together with provision for drainage constitutes the treatment in those cases where one can be reasonably certain that there has been no injury to the peritoneum. In those in which such an injury has occurred, immediate laparotomy is essential.

The case I wish to report is that of a young man of thirty years, employed by a packing company. He was first seen on May 30, 1930, with a history of having two weeks previously slipped and fallen over backwards onto an iron rod which extended upward from a small platform on the floor. The impaling object was apparently about one-half or three-quarters of an inch in diameter. At the time he felt an intense pain about the anus but could discover no wound. After resting for an hour or two he returned to his work. The day following he was fairly comfortable and continued to work. Four days later he again began to have pain about the rectum, and six days after the accident something "broke" and discharged near the anal opening, with a relief of the pain.

Examination showed the opening of a sinus in the skin three-quarters of an inch from the anus in the mid-line posteriorly. A probe passed into the tract proved it to extend for one and a half inches towards the coccyx and slightly to the left. No connection with the rectum could be determined either by means of the probe or by a roentgenogram of the barium-filled tract.

The question at issue was whether the accident bore any relation to the existing sinus, and was a matter of liability. It was felt that this could not be definitely settled, but in any event the treatment of the sinus was surgical.

At operation the tract was carefully explored under sacral anesthesia. As the probe had indicated, it extended upward for about an inch and a half to a point anterior to the sacro-coccygeal joint. At the bottom of the tract a small fragment of cloth was discovered. This measured one-half an inch in diameter, and was of khaki material. No connection with the rectum could be found. The tract was laid open and packed, after which prompt and uneventful healing took place.

Reconstructing the injury and its complications was not difficult in the light of the operative findings. The rod had apparently passed through the anal orifice, with no injury to it, and had then passed upward, perforating the wall of the rectum and coming to rest against the sacrum. As it forced its way through, it carried with a fragment of the man's trousers, which was in all likelihood punched out by the action of the end of the rod against the sacrum. When the rod was withdrawn, the small piece of cloth was left remaining in the wound. The wound in the rectal wall had apparently healed quite promptly, leaving a closed space in which the foreign body lay. After an interval of three or four days sufficient suppuration occurred to cause a rupture of the abscess and a discharge of pus to the outside. The discovery of the cloth in the sinus naturally proved conclusively the relation of the sinus to the original impalement.

FREE JOINT BODIES

REPORT OF TWO UNUSUAL CASES

Wallace H. Cole, M.D.
Saint Paul

One hesitates to add to the already voluminous literature on free joint bodies but the two cases to be reported seem to be so unusual that some available record should be made of them.

The first patient was a middle aged farmer who was seen the day after he had been injured in an automobile accident out in the country. He received first aid for a large laceration over his left eye and for an injury to his right elbow, the elbow being placed in a right-angle splint. This splint was still in place when the patient was first examined in the office. There was no history of any previous disability to the elbow joint, although the patient could remember several times when he had received severe contusions without any disability following. Without removing the splint a radiograph was taken which showed a transverse fracture of the olecranon with what was apparently a foreign body lying between the fragments, but after removal of the splint examination showed no break in the skin of the elbow and a new film demonstrated a free body (Fig. 1). Operation was performed that afternoon and a typical "joint mouse" was found lying between the fragments as shown in the radiograph. The free body was flattened and disc-shaped, measuring about 1.3 centimeters by .6 of a centimeter (Fig. 2). Its surface was slightly lobulated and smooth in the way characteristic of free bodies which have been in joints for some time but there was a small tag of soft tissue attached near one end. Upon cutting the body in two it was found to be very hard but not bony in density. The cut surface seemed to be calcareous and was definitely laminated but no area of true bone was observed (Fig. 3). The tissue was very easily decalcified and microscopic sections showed a cartilaginous mass with areas of calcification. The cartilage was alive and apparently growing (Fig. 4). Recovery from the fracture was uneventful.

Free bodies in the elbow are not uncommon, that joint coming next to the knee in the frequency of this lesion, but on account of its structure the symptom of "catching" or "locking" seen so typically in the knee is frequently lacking. A body can, therefore, be present in an elbow for many years without causing symptoms. The origin of the body under discussion is problematical but the lack of bone seems to rule out the so-called osteochondritis dissecans. Probably either a small flake of articular cartilage had been separated off in the past and had become attached to the synovial membrane near the olecranon fossa, or the fragment started as a small cartilaginous growth from the synovial membrane itself. This had gradually enlarged, receiving its nourishment by means of its attachment as well as from the synovial fluid. At what time the body became free is, of course, problematical but the ragged tag on the "mouse" might indicate that it had been torn loose from its synovial attachment only at the time of the accident. Being free and lying posteriorly in the joint it naturally fell between the fragments of the fracture.

The second patient was a man sixty years of age who, for about two years, had had some indefinite trouble with the right knee which was never severe enough to keep him from work. About a month before he was seen he had a sudden attack of pain in the knee which had caused definite disability since. There was no locking at any time, however, but pain was always present on use of the leg, being centered about the mesial side of the joint. This pain was always relieved by rest.

Examination showed a man with rather marked bow

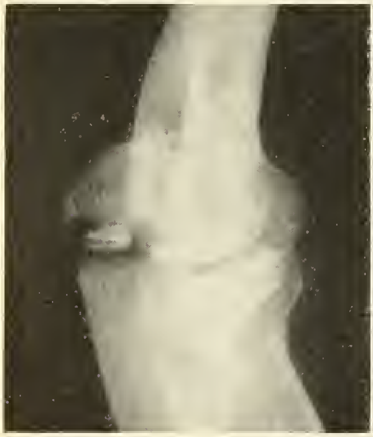

Fig. 1. Lateral radiograph of elbow showing fracture of olecranon process with a free body lying between fragments.

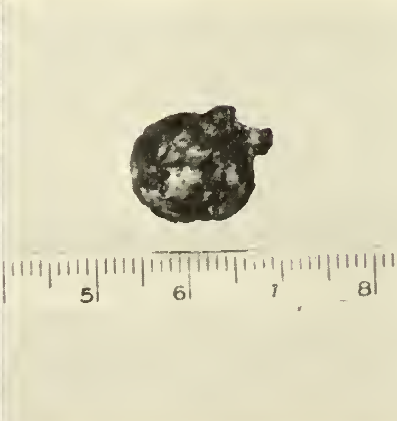

Fig. 2. "Joint mouse" removed from between fragments of fractured olecranon.

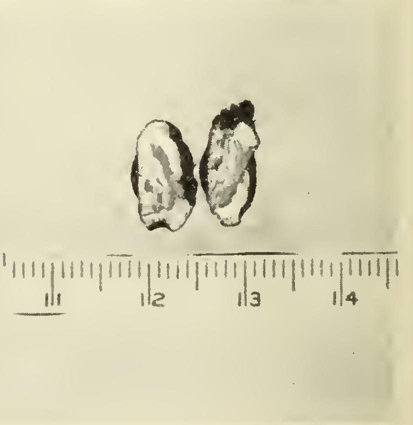

Fig. 3. "Joint mouse" shown in Figures 1 and 2 cut across to show gross appearance. Note laminated structure.

legs but with no definite findings in the knee joints. The region of the mesial collateral ligament of the right knee was indicated as the area where discomfort was felt but no tenderness was present here, although pain was referred to that point on forcing hyperextension of the joint and attempting to increase the varus. Radiograph disclosed a shadow of a free body lying anteriorly and slightly laterally in this joint (Figs. 5 and 6). Although the symptoms had not been in any way typical or even suggestive of a free body it was felt that its presence was the underlying factor in the disability and that there was no question but that it should be removed. On account of its position as shown in the radiograph, that is, very close to the tibia and anteriorly in the joint, a diagnosis of free body under the lateral semilunar cartilage was made, as this condition had recently been reported. At operation the lateral cartilage was exposed and, although a hook was passed beneath its free margin, the body could not be located. Feeling sure of the diagnosis, however, the cartilage was freed from its attachment to the tibia for about 1.5 centimeter, and on lifting it up the body was seen lying loose beneath it.

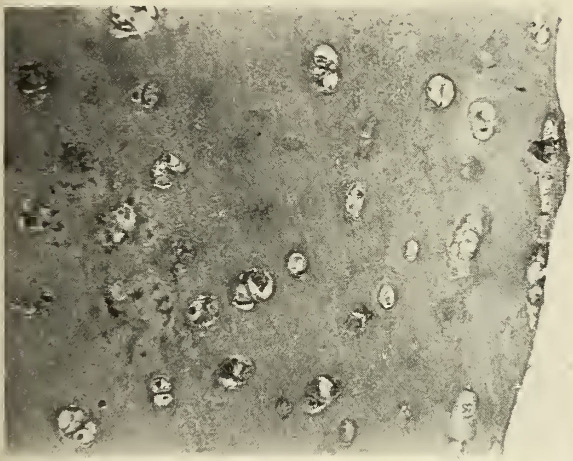

Fig. 4. Photomicrograph of free joint body shown in Figures 1 to 3 showing growing cartilage and areas of calcification.

No source of the body was found at operation, all joint surfaces seen being smooth and normal in appearance. The fragment (Fig. 7) was a typical flattened joint body measuring about 1.4 centimeter by 1.1 centimeter and on section showed no lamination but a bony center with proliferation of cartilage around it (Fig. 8).

Geist has reported two cases of free bodies beneath the lateral cartilage and if it had not been for the knowledge of these the search for such a body as now reported might have been unsuccessful. Although the condition is undoubtedly rare many minutes of anxious searching may be saved if its possibiilty is kept in mind. The origin of the free body in question is problematical as no source was found, but the bone in the center shows the origin might have been from some small fragment broken or separated off in the past from one of the articular surfaces. During the two years of indefinite discomfort in the knee, the body having lodged beneath the lateral meniscus was gradually growing until finally it reached such a size that by some movement or change in position it caused a catch without locking, and a definite disability on weight bearing.

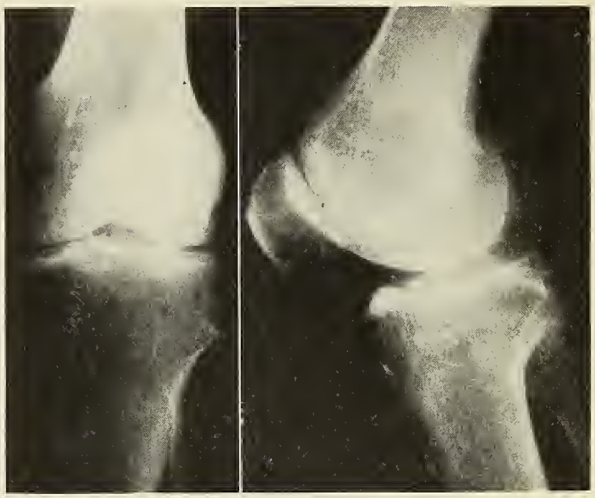

Fig. 5 (Left). Antero-posterior radiograph of knee showing free body lying close to tibia in lateral side of joint. This body is beneath the lateral meniscus.

PRESIDENT'S LETTER

ONE day last month St. Paul and Minneapolis physicians were invited by the Community Chest organizations of the two cities to listen to luncheon speeches on the subject of the Cost of Medical Care.

The speakers in each case were lay public health workers in the employ of the Committee on the Cost of Medical Care. Their remarks were confined to already published studies of the committee.

But it occurred to me to wonder just how it has come about that lay social groups are inviting the medical profession to listen to figures on the cost of medical care.

Why wasn't it the county medical society or the state association that was sponsoring these public luncheons on the subjects relating to medical care?

How did this busy and diversified Community Chest group come to be sufficiently interested in the subject to bring in a speaker at their own expense to tell us about it?

There is unusual interest in medical matters everywhere these days. Pick up any of the first class magazines and you will find at least one, and maybe more articles about the medical profession or about medical costs and the distribution of medical care.

This is obviously the doctor's problem as much as it is anybody's. The doctor has something of value to offer to any discussion of the subject because he alone is dealing intimately with both patients and doctors. But curiously enough these exhaustive medical articles are seldom written by medical men.

The inequality in distribution of medical care is bound up, to a considerable extent, with an economic situation that is beyond the immediate adjustment of either doctor or social worker. But certainly it is the physician's business to be as well informed and as actively interested as the social worker in economic readjustments of the care of the sick. County medical societies ought to be at work on it. Auxiliaries ought to be interested, medical journals ought to be studying it. Physicians ought to be at least as well qualified and as ready to talk about the situation as lay observers.

The fact is that we have now in America a new professional group. The social worker group with its specialized training and its diversified interests that are as wide as all society. These new professional men and women are professionally interested in poverty and sickness. It is only another step—and a step which they make with enthusiasm—to interesting themselves in the medical profession and its problems.

The Committee on the Cost of Medical Care is one practical result of this intelligent, active interest. American Medical Association representatives are participating to some extent in the studies made by the committee. Unfortunately they did not initiate it nor were they party to its organization. The committee has been making exhaustive studies into its subject, supported by lay foundation funds. It will be ready in another year to draw conclusions from the mass of data and to make recommendations. What those recommendations will be, physicians can only guess.

Is the medical profession informing itself, also?

Will it be ready as an interested party to accept or reject these recommendations intelligently?

In this letter I want to urge every county medical society in Minnesota to make a serious, unprejudiced study of the problem of the costs of medical care—if it is a problem—and do it NOW.

The problem of distribution of medical care and costs, which includes, of course, hospital care, nursing, drugs as well as doctors' fees, is one of our problems—the problem of the Minnesota State Medical Association and each of its component societies and its auxiliary organizations, quite as much as of any social service group, however active or inclusive its interest.

It would be a pity, indeed, if the great profession of medicine were ever to be caught in the unfortunate position of giving a reluctant, forced submission to outside reorganization of its own domain—all because it was too short sighted or too busy, or too indifferent to inform itself in time.

L. Sogge

President
Minnesota State Medical Association.

Vol. XIV April, 1931 No. 4

THE STATE MEETING

An afternoon of clinics, led by the best medical talent available in the University of Minnesota medical teaching staff and elsewhere, is announced as the major feature of the seventy-eighth annual meeting of the Minnesota State Medical Association, to be held in Minneapolis, Minnesota, with headquarters at the Nicollet Hotel, on May 5 and 6, 1931.

This interesting departure from ordinary program composition is to occupy the entire Tuesday afternoon session of the meeting. A total of thirty-two clinics will be held in four amphitheaters of the University Hospital and Medical School, which are to be turned over to the State meeting for the occasion.

The remainder of the two-day scientific program will be divided into three main divisions, all to take place at the Nicollet Hotel.

Surgery and obstetrics will occupy the Tuesday morning session. Wednesday morning will be devoted to a Symposium on Diagnosis, and Wednesday afternoon to a Symposium on Therapy similar to the successful symposium that concluded the Duluth program last year.

Among the distinguished visitors who will be present for the meeting are: Dr. George Ward Gray, Jr., Professor of Obstetrics and Gynecology at Cornell University, New York, who will speak as George Chase Christian Memorial lecturer on "Carcinoma of the Uterus" Tuesday morning, and Dr. Drew William Luten, Assistant Professor of Clinical Medicine at Washington University, St. Louis, Mo., who will talk Wednesday morning on "Diseases of the Heart with Special Reference to the General Practitioner."

An important series of clinical demonstrations and exhibits, all of them intimately related to the scientific program, will be on view at the hotel. Among these will be the University of Minnesota, the Mayo Clinic and the State Department of Health exhibits, a tuberculosis demonstration and the display of Brush bacteriological specimens.

The Southern Minnesota Medical Society will again present a gold medal for the best individual contribution to these exhibits, following a precedent set last year.

The Women's Auxiliary of the Minnesota State Medical Association, which holds its annual meeting at the same time, will join with the Medical Association for the annual banquet of the two organizations to be held at the Nicollet Hotel on Tuesday night.

The House of Delegates will meet on Monday night, May 4, at 7:00 P. M. at the Nicollet Hotel. The following are members of the Reference Committee: Dr. J. R. Manley, Duluth; Dr. W. C. Carroll, St. Paul; Dr. H. M. Blegen, Warren;

Dr. C. P. Robbins, Winona; Dr. C. B. Wright, Minneapolis.

The scientific program of the seventy-eighth annual meeting appears in this issue of the Journal. Members are urged to make their plans at an early date so as to be able to attend this meeting.

THE TUBERCULOSIS CAMPAIGN

The annual Early Diagnosis of Tuberculosis campaign, conducted by the Minnesota Public Health Association and its affiliated national body, the National Tuberculosis Association, will focus its attention particularly this year on the period of adolescence.

Special studies made generally over the United States indicate that an alarmingly high percentage of children of the 'teen ages, compared with other age groups, are breaking down with tuberculosis. That this is the weak spot in our defense armor against tuberculosis has long been obvious to the doctor. Any authoritative public education campaign which calls emphatic attention to the dangers surrounding this age and the absolute necessity for early discovery of possible tuberculosis infection has the doctor's sympathy and coöperation.

Tuberculosis in early adulthood undoubtedly has its usual origin in a childhood infection with the disease and too often in an unsuspected long continued contact with open tuberculosis. Early detection of this infection and protection against such contacts, so far as widespread public education can bring about these highly desirable results, are the objectives of this campaign. It has the hearty endorsement of the Minnesota State Medical Association and will, incidentally, enlist the services as speakers of many association members in the course of the campaign.

DR. BIRNBERG'S MOVIE FILMS OF RUSSIA AND HIS COMMENTS*

Strange reports and conflicting conclusions have come from post-war Russian visitors. Most of us have heard lectures by educators, ministers or writers, portraying their travel stories and impressions. It is a pleasure to accord to one of our own members credit for his incomparable industry—in three weeks he covered the area from the Baltic to the Black Sea. For an amateur photographer he showed unusual adeptness—he brought back views of everything from "droschkes" to churches, temples, marriage ceremonies and nude bathing! What his discerning medical eyes singled out his camera brings to his spoken words the most convincing confirmation. When he remarks that the people evidence no unusual undernutrition but plenty of evidence of primitive dress and living he can prove it with his engaging films. He shows the actual cues of people waiting in line with their food cards, which we have heard so much about. At a time of unusual unemployment with us, when various methods are being devised to enable people to eat, it is interesting to note that in Russia the only way one can get a food card is to be gainfully employed or too sick or too old to work! Indeed, everybody works, "including father." Men and women work together, whether it be in digging sewers or in staffing hospitals, with no distinction whatever as to pay but considerable as to diet, since those doing the heavier, manual type of work are given the more invigorating rations. He carefully points out that these restrictions are not on a basis of "class," but according to category—A, B and C—and the doctors, on a basis of mental work, are in Class "C"! In a country which has set itself to abolish all notions of class distinction, he comments that the dining car service he saw on the way to the Crimea defied description, that the cars were divided into the types "hard" and "soft"!

Russia, so violently disturbed, offers a most unusual array of paradoxes; with all their turmoil they are by far the most hopeful present-day Occidental nation. They have so much individual autonomy and yet such extremes of police interference; "a people who use us (perhaps the most capitalistic of all countries) as their example, though they aim by the most violent and extensive of propaganda to destroy the world's principle of individual ownership and to establish Communism."

Dr. Birnberg has brought us some intimate glimpses of the changes that have befallen our medical brethren in Russia. A high grade of medical training and system of apprenticeship has been worked out, all at public expense. A most unusual redistribution of doctors has been worked out, and the younger men are sent to the rural districts. Those who succeed or show research capacity are singled out and helped. The inference is given that those particularly gifted may choose their own types of work and places of abode. With the criticism that is leveled more or less persistently at our general plans and methods of developing specialism, it is interesting that they insist upon three full years of preparation and "a period of four months spent in special research and study every third year." Very large groups of individuals, as well as diseases, may be studied, not only from the disease standpoint but from the economic and social side as well. Their attitude toward the problem of prostitution—with an effort at social and economic adjustment rather than reform—is strikingly suggestive. Apparently Russian medicine has already greatly influenced much of continental Europe. "The whole situation is the most amazing human experiment ever contemplated." Thus, we can see that no matter what happens to Russia in the future the world is never going to be quite the same because of what has already occurred.

---

*A recent address by Dr. Tobias L. Birnberg, St. Paul, with personally taken movie films on the occasion of a visit into Russia in the summer of 1930, and given in the University Extension Course for doctors at Duluth, Feb. 23, 1931.

This whole wretched problem is so engaging, so much mooted, and so unutterably complex, that we should all be most thankful to Dr. Birnberg for his zeal in accumulating his evidence, and his gifted and spirited, as well as unbiased, attitude, in relating his impressions. The address should be heard by all our doctors as well as their families and friends. The suggestion might be passed to the program committee of our State society, so that at our next meeting the data here most inadequately touched upon might be given, provided the good Doctor will consent to do so.

E. L. T.

TOBACCO

On the basis of one national principle that if there is something people like to do there must be some reason why they should not do it, scientific investigators might be expected to have found some reason unqualifiedly to condemn the use of tobacco. On the basis of another national principle that anything advertised with enough millions must be of virtue, it might be expected that these same investigators would have found that abstinence from tobacco is the hidden cause of lack of charm or of virility. But scientific investigators are free of fixed ideas, as long as they remain scientific.

The day may come when it will be a mark of individuality to amble a nonchalant mile for one of a coughless consignment of cigarettes and then secretly to toast it over one's bootleg fire, but that day is not yet. Nor has the time come to educate the young mother that an infusion of tobacco must be mixed with the baby's food for the vitamins therein contained. Consequently, the perennial question of the harmfulness of nicotine, "pyridine and other pyrogenous compounds, carbon monoxide, traces of hydrocyanic acid, phenols and aldehydes" continues to bloom with the violets, and in between. And it should, for the problem needs solution.

The effects, not of nicotine only, but of the several chemical substances just mentioned, alone or together, must be considered when tobacco is smoked. Also, where it is grown, how it is cured, whether it is moist or dry, how fast it is smoked, how slowly, how it is wrapped, or what kind of a pipe is used, enter into the question. Moreover, the smoke may be inhaled or puffed, and tobacco may not be smoked at all. Tobacco may be, at least it used to be, chewed, whether or not circumstances would allow of expectoration. Doubtless all physicians can remember certain hirsute males who boasted that they ate theirs. As the biometrician might say, several variables seem to be involved.

Since these variables are not likely to be brought into correlation by the advertising writers and the physicians who help them with their copy, let us see what opinions a few of the serious seekers have evolved. In 1927 a small volume, written by Schrumpf-Pierron was published under the auspices of the Committee to Study the Tobacco Problem. The bibliography contained 750 names, more or less. Schrumpf-Pierron's conclusions were, in part, as follows: The study of the action of tobacco on the organism is still incomplete, both scientifically and clinically; sound individuals and unsound individuals react differently; immoderate doses cause disturbances that are first functional, then organic, and some of them are grave; disturbances have increased in frequency as the consumption of tobacco, particularly of cigarettes, has increased; the cigarette habit leads readily to abuse; further studies are needed, particularly "statistical research as to the influence of tobacco as ordinarily used among large groups of people as compared to the effect of abstinence among similar groups."

That does not give much of a chance for either the reformers or the copy writers to attack the subject from the health angle. The investigation, however, is being carried on.

W. E. Dixon, pharmacologist at Cambridge University, has studied the subject of the tobacco habit. He concluded his Norman Kerr lecture with the statement that smoking "leads to digestive and circulatory disturbances." He gave expression to an impression of clinicians that many years of continuous absorption of nicotine is responsible for some cardio-vascular conditions of middle life and old age. However, he continued, "It may well be that living in a civilization such as ours, under the conditions of strain imposed by residence in cities, the ordinary man shows in his nervous responses variations from the normal, and on such tobacco exerts a beneficial function."

Rolleston has in a sense carried on the work of Schrumpf-Pierron by collecting from the literature the views of thirty-four writers on the effects of tobacco. He did not come to conclusions. Who could?

It is not easy to see how a study could be prosecuted more scientifically than that of Diehl, of the University of Minnesota. He had a group of 445 smokers and one of 441 non-smokers. The work was analyzed by biometric methods. However, as Diehl pointed out, the subjects were too young to have suffered from degenerative changes, if tobacco is responsible for any. He found that the smokers had less stable cardio-vascular systems than non-smokers. However, he was careful to state that "the effect of such a difference on health or longevity never has been determined." The final rating of the two groups for classification for physical activities were not significantly different.

Another relevant piece of work done in Minnesota is concerned with the old question of tobacco and thrombo-angiitis obliterans. Barker studied the consumption of tobacco by 350 patients between the ages of twenty-five and fifty-five years, who had thrombo-angiitis obliterans and who had been seen in The Mayo Clinic in the last ten years. He compared with this group another that corresponded with the first in every way except that the members of it did not give evidence of peripheral vascular disease. He found reason to believe that tobacco is not the primary cause of thrombo-angiitis obliterans, but that it may be a predisposing cause. Moreover, if patients with thrombo-angiitis obliterans have used tobacco excessively, the condition seems likely to run a more malignant course. Barker expressed the belief that evidence favors prohibition of the use of tobacco to patients with thrombo-angiitis obliterans, but, he added, "the data are by no means conclusive."

W. J. Mayo, who never has used tobacco, in discussing Barker's report, gave the present status of the tobacco problem as well as it can be stated: "I have no evidence to show that a moderate use of tobacco is harmful to the average person, but we know that even what might be called moderate smoking is harmful to some persons. On the whole, smoking seems a habit which has possibilities for harm, and has little to its credit, although many seem to derive a good deal of comfort from it, especially those persons who have nothing to do at the time which interests them more. Pipe smoking should be the least harmful, because the pipe is usually out, and the smoker is just as happy until he notices the fact, which depends largely on how much interested he is in what he is doing. The pipe seems to be the adult pacifier which takes the smoker back to his childhood days.

"Some smokers, especially of strong cigars, have functional heart trouble, and it now appears that the cigarette smoker is subject to various ills. I doubt that much harm results to the person who smokes a cigarette only occasionally."

From all that has been done thus far, it seems that "T. M." means both "'tis mince" and "'tain't mince." The Governor of North Carolina and the Governor of South Carolina each must have been an excellent judge of good liquor. One said there was iron in the whisky; the other said, leather. When the barrel had been drained, they found in the bottom a loose tack, just under the head of which was a leather gasket. Yet it is not recorded that either governor died of hepatic cirrhosis. Nor is the opposite on record, for the story is fictitious.

We need the facts about cirrhosis. We also need them about the effect of tobacco. All encouragement to those who are seeking them, and caution to those who are inclined to jump to conclusions.

R. M. Hewitt, M.D.

NEW AND NON-OFFICIAL REMEDIES

The following articles have been accepted by the Council on Pharmacy and Chemistry:

Abbott Laboratories
- Ampules old Sodium Thiosulphate-Abbott, 0.01 Gm.

Arlington Chemical Co.
- Grass Mixture No. 1 Pollen Extract-Arlco (Timothy, June Grass, Orchard Grass, Red Top, in equal parts); Grass Mixture No. 2 Pollen Extract-Arlco (Timothy 40 per cent, Orchard Grass, Red Top, and Sweet Vernal Grass, each 15 per cent); Grass Mixture No. 3 Pollen Extract-Arlco (Bermuda Grass and Johnson Grass in equal parts); Ragweed Dwarf and Giant Mixture Pollen Extract-Arlco (equal parts of each); Birch Mixture Pollen Extract-Arlco (White Birch, Black Birch, Yellow Birch in equal parts); Maple Mixture Pollen Extract-Arlco (Red Maple, Ash-leaved Maple, Norway Maple, Sugar Maple in equal parts); Oak Mixture Pollen Extract-Arlco (White Oak, Red Oak, Black Oak, Swamp Oak in equal parts)

Fairchild Bros. & Foster
- Liver Extract-Fairchild

Eli Lilly & Co.
- Tablets Amytal, ¾ grain

H. A. Metz Laboratories
- Sulpharsphenamine-Metz, 0.75 Gm. Ampules
- Sulpharsphenamine-Metz, 0.9 Gm. Ampules
- Sulpharsphenamine-Metz, 3.0 Gm. Ampules

G. D. Searle & Co.
- Procaine Borate-Searle
- Ampules Procaine Borate and Epinephrin 1 c.c.

Health Products Corporation
- Marine Liver Extract (White)

Schering Corporation
- Iopax

The following articles have been exempted and included with the List of Exempted Medicinal Articles (New and Non-official Remedies, 1930, p. 477):

Chas. Pfizer & Co.
- Cinchophen-Pfizer

G. D. Searle & Co.
- Ampules Sodium Thiosulphate (Searle) 5 c.c. +
- Ampules Sodium Thiosulphate (Searle) 10 c.c. +

TRUTH ABOUT MEDICINES

The following products have been accepted by the Council on Pharmacy and Chemistry of the American Medical Association for inclusion in New and Non-official Remedies:

Procaine Borate.—A borate formed by the interaction of *p*-aminobenzoyl-diethylaminoethanol (procaine base) and boric acid. It contains 58.1 per cent of *p*-aminobenzoyl-diethylaminoethanol. Procaine borate closely resembles procaine hydrochloride in its actions and uses. When injected subcutaneously, procaine borate exerts a prompt and powerful anesthetic action. It is non-irritant. Its action is enhanced by the addition of a small amount of epinephrine, as in the case of procaine hydrochloride.

Procaine Borate-Searle.—A brand of procaine borate-N.N.R. It is also supplied in the form of ampules procaine borate and epinephrine 1 c.c., containing procaine borate-Searle 0.0216 Gm. and epinephrine 0.00017 Gm. in 1 c.c. G. D. Searle & Co., Chicago.

Liver Extract-Fairchild.—A complete concentrate of an aqueous extraction of fresh edible liver, freed of connective tissue, lipoid, and heat-coagulable protein. It is marketed in vials, each containing the material derived from 100 Gm. of fresh liver. Liver extract-Fairchild is used in the treatment of pernicious anemia. Fairchild Bros. & Foster, New York. (Jour. A. M. A., February 14, 1931, p. 529.)

Marine Liver Extract-White.—A liver extract representing the water-solutble fraction obtained from the livers of fish of the Gadus family in a glycerol-water solution. 100 c.c. represents fresh liver, 3,027 Gm. (1 fluidounce represents 2 pounds avoirdupois). Controlled clinical observations show that in pernicious anemia rapid improvement may be expected following the administration of marine liver extract-White. Health Products Corporation, Newark, N. J.

Pollen Extracts-Arlco.—The following pollen extracts-Arlco (New and Non-official Remedies, 1930, p. 29) have been accepted: Grass Mixture No. 1 Pollen Extract-Arlco; Grass Mixture No. 2 Pollen Extract-Arlco; Grass Mixture No. 3 Pollen Extract-Arlco; Ragweed Dwarf and Giant Mixture Pollen Extract-Arlco; Ragweed Mixture Plus Burweed Marsh Elder Pollen Extract-Arlco; Spiny Amaranth Pollen Extract-Arlco; Western Water Hemp Pollen Extract-Arlco. Arlington Chemical Co., Yonkers, N. Y. (Jour. A. M. A., February 21, 1931, p. 613.)

ACCEPTED DEVICES FOR PHYSICAL THERAPY

The following has been accepted by the Council on Physical Therapy of the American Medical Association for inclusion in its list of Accepted Devices for Physical Therapy:

National Vaporizer.—This apparatus is designed for the purpose of vaporizing oil or aqueous solutions and atomizing very fine impalpable powders. The apparatus contains no metal valves or parts that may oxidize or stick together. It is so constructed that it enables almost the entire solution to be vaporized. The apparatus is relatively fragile. National Drug Co., Philadelphia. (Jour. A. M. A., January 24, 1931, p. 271.)

A PAGE FORUM OF THE COMMITTEE ON PUBLIC HEALTH EDUCATION

Advertising and the Doctor

"Although the great American god 'Advertisia' apparently controls most of our activities and our interests, it has not thus far succeeded in gaining a complete overlordship in the field of medicine. True, the use of the health claim for the advertising of antiseptics, tooth pastes, foods and most household utilities has become a popular means of approach to the 'health-conscious' public. True, some clinics still promote their services to the indigent and the middle class by extensive announcements in the public press; for this, however, the plea of holy charity is used in extenuation. Again and again, advertising agents seeking some new outlet for the practice of their art have developed campaigns to be financed by medical societies or by individual physicians with a view to placing the wares of the medical profession before the public, as the services of musicians, plumbers, electricians and bakers are advertised. Thus far few medical societies of importance have succumbed to the lure of such promotions.

"Medical education of the public is just as much a function of the press as education in the rules of contract bridge, the technic of golf or the proper training of children. The threat of any newspaper that it will omit scientific news of importance in the field of medicine unless physicians purchase advertising space is an idle threat. Any newspaper worthy of the name must publish scientific news. The vast majority of competent editors are convinced that few other news items are of equal significance at the present day. The newspaper that is dominated in its news columns by its advertising department is on the road to ruin." (From the *Journal of the American Medical Association,* March 7, 1931.)

A Job for the Physician-Writer

"The Socialization of Medicine" is the title of the newest volume in the interesting little series called "The Reference Shelf," published, according to its sponsors, for the purpose of making "available, when in need of good debates, collections of articles, briefs, bibliographies, and study outlines on timely subjects for public discussion."

Publication in the series is irregular because the object is to make the material available in each instance at the time when there is the greatest need."

Apparently, then, the greatest need had arrived for a debate upon the socialization of medicine, since a volume on this subject is only now hot off the H. W. Wilson press.

Compiled by Edith M. Phelps, author of a number of similar contributions on civic subjects, this little book follows a standard procedure, presenting briefs for and against socialized practise of medicine followed by general, affirmative and negative discussion clipped from the current periodical publications.

It is interesting to note that the advocates of a socialized reorganization of medical practise are quoted from a variety of important lay publications, the *Nation*, the *North American Review*, the *Century*, the *Scientific Monthly*, and *Harpers*.

The opponents of socialization, on the other hand, being chiefly representatives of organized medicine, have apparently limited their arguments mostly to the columns of their own professional magazines, which are seldom, if ever, picked up by lay readers.

If the attitude of organized medicine is important enough for the compiler of this volume to dig out of the professional journals and line it up against the facile and diversified discussion on the opposing side of the subject in lay literary publications, it may be important enough to take its chance in the columns of these publications in the first place. Otherwise it can have little access to the intelligent lay public which perforce hears very little on the subject beyond the doctrinaire medico-social workers' rosy dream of a new world healed of standardized ills by a standardized group of government healers.

OF GENERAL INTEREST

Dr. C. A. Boreen, of Minneapolis, was recently elected president of the Minnesota Dermatological Society.

Dr. Charlotte Stickney has opened offices in the Granite Exchange Building at St. Cloud, Minnesota. Her practice is limited to Pediatrics.

Dr. Nelson W. Stewart, formerly of North Mankato, has moved to Lead, South Dakota, where he is associated with the Homestake Hospital.

Dr. J. F. Smersh of Owatonna has been appointed secretary of the Steele County Medical Society to fill the vacancy caused by the death of Dr. A. B. Hart.

Dr. Brandt Leopard, who has been located at St. Cloud for the past year with Dr. Richards, has left for Evanston, Illinois, where he will associate himself in practice with Dr. Benjamin Huggins.

The Bratrud Clinic have moved from Warren, Minnesota, to Thief River Falls, Minnesota, and occupy part of the first floor of the new St. Luke's Hospital. Dr. Edward Bratrud is Chief of Staff. Dr. A. M. Smith, formerly of St. Paul, is associated with the Bratrud Clinic as head of the X-ray Department.

MONUMENT FOR DR. MILLARD

In a recent communication from Dr. E. S. Boleyn of Stillwater attention is called to the fact that the grave of Dr. Perry H. Millard in the Stillwater cemetery is entirely unmarked.

Dr. Millard's memory has been honored and perpetuated by the University itself in Millard Hall. It would seem fitting in view of Dr. Millard's outstanding services to the medical profession of the state and considering his long services as dean of the medical school that the medical alumni acknowledge these services by a small contribution towards the erection of a suitable monument for his grave.

The undersigned committee requests that each medical alumnus of the University of Minnesota send his check for $1.00 to Dr. J. T. Christison, Hamm Building, St. Paul, Minnesota, for the erection of a suitable monument.

Recently the organization of the Medical Alumni of the University contributed the sum of $25.00 to initiate the undertaking.

There is no money available from Dr. Millard's estate for this purpose and the Legislature has declined to make appropriations for the same purpose. Your committee feels that in asking for a small contribution no hardship will be caused anyone and that in honoring Dr. Millard's memory in this manner we honor the medical profession of the state.

W. F. Braasch, Rochester
E. S. Boleyn, Stillwater
J. T. Christison, St. Paul
F. A. Erb, Minneapolis
E. L. Tuohy, Duluth
N. O. Pearce, Minneapolis

OBITUARY

Dr. Elias P. Case

1849-1930

Word has been received of the death of Dr. Elias P. Case, December 23, 1930, at his home in Oakland, California, at the advanced age of 81 years.

He came to Minnesota as a child with his parents in the early fifties, where the family lived on a farm north of Wells Lake. As a young man he drove horses for Dr. N. M. Bemis, one of the first physicians in Faribault, and studied medicine under him.

He married Emma A. Nutting, second white child born in Faribault, the date of her birth being February 17, 1856. She was the daughter of Truman and Mary Nutting, who kept the first hotel in Faribault.

In 1888 Dr. Case went to Europe, where he spent two years studying surgery in the hospitals of Germany and England.

Dr. Case and his family made their home for twenty-five years in Waterville, where he was one of the leading physicians of the community. In 1890 he built the hospital known as the Samaritan Home on the north shore of Lake Sakatah. This he operated with marked success until the hospital was destroyed by fire.

About the year 1905 the family moved to Corning, California. His wife died there in 1911. Since that time he has practiced his medical profession in Oakland, California. Two sons and a daughter survive him: Mason N. Case of Los Angeles, California; Alex T. Case and Miss Abbie Case of Oakland, California.

SCARLET FEVER TOXIN

The Dick scarlet fever toxin is regarded as a safe and efficient immunizing agent against scarlet fever. The main drawback to its use appears to be that several injections, generally not less than five, must be given before such a degree of immunity is established that the subject no longer gives a positive Dick test. (Jour. A. M. A., February 21, 1931, p. 633.)

CONSULTATION BUREAU

Wm. A. O'Brien, M.D., ***Director***
Minnesota State Medical Association
11 West Summit Avenue
Saint Paul, Minnesota

1. *Question.*—Would appreciate learning what nonsurgical treatment can be tried to help a case of procidentia in a female 28 years old. The rectal (anal) sphincter is quite relaxed so that involuntary escape of gas is bothersome. Mineral oil can not be taken for the attendant constipation because of leakage. There are no polypi or hemorrhoids present. Prolapse has been coming on for six years. Does surgery now offer good prospects for cure? Is cauterization of rectal mucosa with actual cautery or chemicals a wise procedure? Are the results worth the trial?

   Answer.—In young women surgical treatment offers a good prospect of cure. In older women who cannot have the operation for one reason or another, the ordinary ring pessary may bring relief. You did not state whether or not the trouble was due to laceration incident to delivery. Sometimes relaxation of the anal sphincter is due to lesions of the spinal cord, especially spina bifida. Not all people with spina bifida have neurotrophic lesions, incident to the defect. Approximately 5 per cent of all white adults have a failure of fusion in either the lumbar or sacral vertebræ. If, in addition, the superficial layers are adherent to the deeper structures, a perforation by a dense band of fatty tissue exists or a bulging of the dura, exostosis of canal, tumor-like nodules composed of fibrous muscle and fatty tissue or nerve degeneration is present, neurotrophic effects may result.

2. *Question.*—I have a patient on whom a diagnosis of benign polyp of the stomach has been made. The tumor partially obstructs the pylorus at times, but otherwise the patient is in fair condition. Only a few gastric complaints are to be be found on careful questioning. What are the chances of this growth becoming malignant, and what should the treatment be?

   Answer.—Benign polyps of the stomach are being reported with increasing frequency. Although less than 100 are on record, many more have probably not been recorded. The average age of appearance of symptoms is between 50 and 60 (although the growth may have been present several years). Certain observers have noted a gradual transition between chronic gastritis, adenoma (polyp) and malignancy. Such growths have been produced experimentally by the use of certain irritants. Malignant transformation has been found in from 12 to 20 per cent of reported cases. Another feature which is of interest is the practically constant finding of achylorhydria with diarrhea (probably due to the absence of hydrochloric acid). Multiple polyps may be present, but if it can be demonstrated that only a small group are to be found, a partial gastrectomy is indicated. Gastric operative specimens have been observed showing both benign tumors and malignant changes.

3. *Question.*—I am going to read a paper at our staff meeting on the subject of postmortem examinations. Can you refer me to some recent publications on this subject?

   Answer.—A fine series of articles may be found in the Bulletin of the American College of Surgeons, XIV, 40:50 (December), 1930. The one entitled, "Means of Securing Postmortem Examinations," by Ralph G. Mills, M.D., Fond du Lac, Wisconsin, is especially recommended for consideration. The subject of the ways and means of securing postmortem examinations is becoming very popular, and a great amount of time and attention is being devoted to the psychological aspects of the question. When it is recalled that the number required by the various governing organizations for recognition is about the same as can be obtained by simply asking the relatives, it is appreciated that many hospitals can have much better records. There is a tendency at the present time to emphasize the actual number of autopsies or the percentages to be obtained. The quality of these examinations is equally important and should not be lost sight of in the scramble to get under the wire with the required percentage. The reasons for the examination may be summarized as follows: (1) Is the patient alive or dead? (2) Does contagious disease exist? (3) Is inherited disease present? (4) What is the cause of death? (5) disciplinary effect on all; (6) teaching; (7) to render justice; (8) to unearth scandal; (9) vital statistics; (10) insurance claims; (11) study of any rare or unusual disease; (12) to evaluate diagnostic methods; (13) scientific discovery; (14) better embalming; (15) the study of the disease (most important of all). The average work-up given to patients in most hospitals today should result in correlation between the main disease and the autopsy findings in about 85 per cent of the cases. The cults have used the old figure of 50 per cent for some time to show up the medical profession. It is to be recalled that this is based on records compiled more than twenty years ago and much progress has been made since that time. You are to be congratulated for your interest in this most "live" subject. It is recommended as a discussion theme for every staff meeting at least once a year. It is only by bringing the subject constantly before the attention of all staffs that good results can be obtained. Most autopsy permissions depend on good service rendered to the patient, and the development of any uncertainty which the family has in regard to the illness. In this way good care and attention to the patient are stimulated, and the family derives a greater satisfaction from a complete report which is possible only when an autopsy examination is conducted.

4. *Question.*—I have been asked to make a talk before a meeting of country school officers on health problems. I wonder if you have any reprints or material of any kind available that might be useful in preparing something appropriate and significant for a meeting of this kind.

   Answer.—The following articles are recommended: "Progress and Prospect in School Health Work," School Health Studies, No. 10, Department of the Interior, Bureau of Education, 1925; "Teaching Health to Ten Thousand Children," Hygeia, November, 1930; "The Classroom

(Continued on Page 370)

MISCELLANEOUS

MINNESOTA STATE BOARD OF MEDICAL EXAMINERS

"HEALTH TEACHER" CONVICTED OF VIOLATING MANITOBA MEDICAL ACT

On Friday, January 9, 1931, John Hugh Lally, formerly of St. Paul, Minnesota, was found guilty of treating persons contrary to the provisions of the Medical Act of Manitoba, Canada. The conviction took place at Winnipeg. Lally was fined one hundred dollars and costs.

Lally operated an office at the St. Paul Hotel, St. Paul, during the month of November and departed rather hastily from the State after the State Board of Medical Examiners instituted an investigation of his activities.

The Minnesota Board co-operated with the Manitoba authorities with the above result.

In February, 1929, Lally was convicted of the same offense at Chicago, Illinois.

ST. PAUL NATUROPATH FINED FIVE HUNDRED DOLLARS

State of Minnesota vs. William H. Hirst (two cases)

William H. Hirst, fifty-three years of age, self styled naturopath, entered pleas of guilty on February 26, 1931, to two indictments charging him with maintaining an office and using the title "Doctor" in violation of the Basic Science Law.

The Hon. John W. Boerner, Judge of the District Court, sentenced Hirst to pay a fine of $500 or serve six months in the Work House for maintaining an office at 138 E. 6th St., St. Paul. Hirst paid the fine and on the other indictment charging him with using the title of "Doctor" Hirst was sentenced to a term of one year in the Workhouse, which sentence was suspended on the unqualified condition that Hirst refrain from practicing healing in any way, shape or manner in the State of Minnesota. Judge Boerner informed Hirst that if any report came to the Court that he was practicing he would be committed to the Work House without a trial. A third indictment charging Hirst with performing an abortion was filed due to the disappearance of the girl who was the star witness for the State. Hirst has been maintaining an office in St. Paul for the past fifteen years and has been quite active in the attempt of the naturopaths to secure recognition in this State. Hirst has been in the limelight considerably during the past two years following the shooting of Lieutenant Miller in an alleged quarrel over a girl. Hirst told the Court that he was married and the father of two children.

Mr. Brist, attorney for the State Board of Medical Examiners, reports very splendid coöperation from Michael F. Kinkead, County Attorney, and his staff, particularly Mr. Lynch and Mr. Bratter; also from Thomas A. Brown, chief of police. Judge Boerner is to be commended for the very rigid terms specified in connection with Hirst's refraining from re-entering the practicc of healing in the State of Minnesota.

REPORTS AND ANNOUNCEMENTS OF SOCIETIES

MINNESOTA STATE MEDICAL ASSOCIATION

78th Annual Meeting

SCIENTIFIC PROGRAM

Tuesday Morning, May 5, 1931
Ball Room, Nicollet Hotel
Minneapolis, Minnesota

SYMPOSIUM ON OBSTETRICS

8:30	Pre-natal Care.	M. C. Bergheim, Hawley
8:45	Recurring Pre-eclamptic Toxemia; Its Clinical Significance.	R. D. Mussey, Rochester
9:00	Accidents of Labor.	J. R. Manley, Duluth
9:15	Infections.	L. W. Barry, St. Paul
9:30	Toxic Neuronitis in Pregnancy.	N. J. Berkwitz, Minneapolis
9:45	Discussion.	J. C. Litzenberg, Minneapolis
10:00	Intermission.	
10:15	Recent Developments in the Management of Duodenal Ulcers.	D. C. Balfour, Rochester
10:30	Carcinoma of the Uterus.	George Ward Gray, Jr., Professor Obstetrics and Gynecology, Cornell University, New York
	George Chase Christian Memorial Lectures	
11:00	When Does Disease Begin?	Charles H. Mayo, Rochester

UNIVERSITY OF MINNESOTA CLINICS

Tuesday Afternoon, May 5, 1931
1:00 P. M. to 5:45 P. M.

A. Room 129, Millard Hall, 160 seats

1:00 P. M.	Surgery	James M. Hayes
1:30 P. M.	X-ray Diagnosis	Leo G. Rigler
2:00 P. M.	Heart	S. Marx White
2:30 P. M.	X-ray Therapy	K. W. Stenstrom and Cyrus O. Hansen
3:00 P. M.	Intermission	
3:15 P. M.	Neurology	Arthur S. Hamilton
3:45 P. M.	Surgery	Arthur A. Zierold
4:15 P. M.	Arthritis	B. J. Clawson and Macnider Wetherby
4:45 P. M.	Pneumonia	Hobart A. Reimann

B. Room 102, Institute of Anatomy, 226 seats

1:00 P. M.	Medicine	Moses Barron
1:30 P. M.	Kidney	E. T. Bell
2:00 P. M.	Kidney	Hilding Berglund
2:30 P. M.	Heart	George E. Fahr
3:00 P. M.	Intermission	
3:15 P. M.	Diabetes	Archie H. Beard
3:45 P. M.	Blood	Frederick H. K. Schaaf
4:15 P. M.	Malignancy	O. J. Campbell
4:45 P. M.	Medicine	Reuben A. Johnson

C. Eustis Amphitheater, University Hospitals, 160 seats

1:00 P. M.	Cancer Gynecology	George Gray Ward, Jr.
1:30 P. M.	Pediatrics	F. C. Rodda
2:00 P. M.	Orthopedics	Wallace H. Cole
2:30 P. M.	Pediatrics	F. J. Huenekens
3:00 P. M.	INTERMISSION	
3:15 P. M.	Heart (Children)	M. J. Shapiro
3:45 P. M.	Dermatology	H. E. Michelson
4:15 P. M.	Plastic Surgery	Harry P. Ritchie
4:45 P. M.	Pediatrics	C. A. Stewart

D. Todd Amphitheater, University Hospitals, 160 seats

1:00 P. M.	Eye	Frank E. Burch
1:30 P. M.	Heart	Henry L. Ulrich
2:00 P. M.	Ear, Nose and Throat	Horace Newhart
2:30 P. M.	Malignancy	W. T. Peyton
3:00 P. M.	INTERMISSION	
3:15 P. M.	Surgery	Owen H. Wangensteen
3:45 P. M.	Obstetrics	R. T. LaVake
4:15 P. M.	Gynecology	John A. Urner
4:45 P. M.	Urology	C. Donald Creevy

Note: Make your selection now of the clinics you desire to attend. The last five minutes of each clinic period will be devoted to questions. Changes between rooms can also be made at this time. For your information clinic A is varied, B chiefly medical, C chiefly pediatrics and D chiefly surgical. If you have any special interest, e.g. heart disease, pediatrics, etc., it will be possible for you to attend every clinic by going from one room to another. There are no duplicate subjects at any time (e.g. 3:15 P. M. neurology, diabetes, pediatric heart disease and surgery). Study the list very carefully and plan your schedule now so that you will not be disappointed. Thirty-two clinics are to be presented in all. Patients will be used as much as possible. This is an opportunity presented by very few State Medical organizations, and we are proud that we have so much talent among our membership.

WEDNESDAY MORNING, MAY 6, 1931
Ball Room, Nicollet Hotel

8:30 Common Mistakes in Ocular Diagnosis.
JOHN M. ROBINSON, Duluth

8:45 A New and Effective Non-Surgical Method for the Treatment of Chronic Suppuration of the Middle Ear.
CHARLES HYMES, Minneapolis

9:00 Traumatic Abdomen. ROY RAITER, Cloquet

9:15 Tuberculin Testing. J. A. MYERS, Minneapolis

9:30 Disease of the Heart with Special Reference to the General Practitioner.
DREW WILLIAM LUTEN, Asst. Prof. Clinical Medicine, Washington University, St. Louis, Missouri

10:00 INTERMISSION (Installation of Officers)

SYMPOSIUM ON DIAGNOSIS

10:10 General Physical Examination.
E. L. TUOHY, Duluth

10:30 Intravenous Urography.
WILLIAM F. BRAASCH, Rochester

10:45 The Value of X-ray Examination of the Chest. W. H. UDE, Minneapolis

11:00 The Value of X-ray Examination of the Stomach and Gall Bladder.
H. M. WEBER, Rochester

11:15 Indications for Examination of the Colon.
E. L. GARDNER, Minneapolis

11:30 Indications for Examination of Genito-Urinary Tract. F. E. B. FOLEY, St. Paul

11:45 Indications for Spinal Puncture.
H. W. WOLTMAN, Rochester

WEDNESDAY AFTERNOON, MAY, 1931

SYMPOSIUM ON THERAPY

1:30 Poliomyelitis. J. C. MCKINLEY, Minneapolis

1:45 Trichomonas Vaginalis Vaginitis.
R. J. MOE, Duluth

2:00 Appendicitis. F. C. SCHULDT, St. Paul

2:15 Salpingitis. W. H. RUMPF, Jr., St. Cloud

2:30 Empyema. S. W. HARRINGTON, Rochester

2:45 Sinus Infections. E. R. BRAY, St. Paul

3:00 INTERMISSION.

3:15 Complications and Results of Prostatectomy.
T. H. SWEETSER, Minneapolis

3:30 Involutional Psychosis.
E. M. HAMMES, St. Paul

3:45 Fracture of the Wrist.
C. A. NEUMANN, Winona

4:00 Fracture of the Hip. A. R. COLVIN, St. Paul

4:15 Fracture of the Humerus.
H. W. MEYERDING, Rochester

4:30 Fracture of the Ankle.
J. S. HOLBROOK, Mankato

WOMEN'S AUXILIARY PROGRAM

Tuesday, May 5

Registration, Nicollet Hotel

Executive Board Luncheon, 12 o'clock, Nicollet Hotel

Executive Board Meeting following the luncheon, Nicollet Hotel

Banquet, 7:00 P. M., Nicollet Hotel

Wednesday, May 6

Annual Meeting, 10 A. M., Medical Arts Building Auditorium

Annual Luncheon, 1:30 P. M., Minneapolis Woman's Club—Followed by program of music and speaking

---

MEDICAL BROADCAST FOR THE MONTH

The Minnesota State Medical Association Morning Health Service

The Minnesota State Medical Association broadcasts weekly at 11:15 o'clock every Wednesday morning over Station WCCO, Minneapolis and Saint Paul (610 kilocycles or 370.2 meters).

Speaker: William A. O'Brien, M.D., Associate Professor of Pathology and Preventive Medicine, Medical School, University of Minnesota.

The program for the month of April will be as follows:

April 1—Health Education (Third Anniversary).
April 8—High Blood Pressure.
April 15—Health in the Home.
April 22—Nervous Exhaustion.
April 29—Cancer of the Kidney.

MINNESOTA SOCIETY OF INTERNAL MEDICINE

The Tenth Semi-Annual Meeting of the Minnesota Society of Internal Medicine will be held in the Eustis Amphitheater at the University April 13, 1931.

The fourth prize of $250.00 will be awarded by the Minnesota Society of Internal Medicine "to the practicing physician, exclusive of Members of this Society, in the State of Minnesota, who has been deemed most worthy to receive a prize in research in clinical medicine."

All physicians who are in active practice and who are legal residents of Minnesota may become candidates for the award. Physicians employed in government service are eligible if their legal residence is the State of Minnesota. Physicians who are whole-time teachers or research fellows in teaching institutions may not become candidates for this prize.

All inquiries should be addressed to, and these should be submitted to the committee before October 1, 1931.

E. T. F. Richards, Chairman,
Hamm Building, St. Paul, Minn.

PAN AMERICAN MEDICAL ASSOCIATION

The third congress of the Pan American Medical Association will be held in Mexico City, July 26-31, 1931, under the auspices of the government of the Republic of Mexico.

The purpose of the Association is to promote a more intimate understanding between the medical men of North and South America. An effort is being made to further medical contacts between English, Spanish, French and Portuguese speaking physicians of Pan America, and a cordial invitation is extended to all physicians interested.

This meeting affords an opportunity for physicians in this country to pay a visit to our sister republic; a trip which has become more and more popular in the last few years.

Officers of the association are: Dr. Francisco M. Fernandez, president; Dr. J. E. Lopez-Silvero, executive secretary; and Dr. Conrad Berenz, treasurer. General offices are at Havana, Cuba.

Further information may be obtained by addressing Dr. Francisco de P. Miranda, Executive Secretary of the Organization Committee, Departmento de Salubridad Publica, Mexico City, Mexico.

WRIGHT COUNTY SOCIETY

The Wright County Medical Society held their first quarterly meeting at the office of Dr. William Hart of Monticello, January 29, 1931.

Dr. W. A. O'Brien and Dr. W. T. Peyton, both of the University, discussed the pathology of the thyroid and its surgical treatment. The subject was handled in the light of recent scientific findings and aroused a great deal of interest. The masterly presentation by the speakers gave evidence that they had the subject well in hand. Several cases were presented by doctors of Wright County. The third speaker, Mr. A. G. Stasel, manager of the Nicollet Clinic, gave a very instructive and interesting talk on credits and collections. The keenness with which he presented his subject aroused sufficient interest in credit and collection methods to result in a committee being appointed to arrange for a doctors' independent credit bureau to be established in Wright County.

Reading of the minutes of the October meeting of 1930 was postponed until the second quarterly meeting which will be held at Annandale, Minnesota, April, 1931.

The ladies were entertained by Mrs. Frank Ellison, of Monticello. A splendid supper was served at the residence of Dr. and Mrs. Hart.

The meeting adjourned.

C. L. Roholt, *Secretary.*

WOMEN'S AUXILIARY
Minnesota State Medical Association

President—Mrs. S. S. Hesselgrave, St. Paul
Chairman Press and Publicity—Mrs. E. A. Meyerding, St. Paul
Editor—Mrs. A. A. Passer, Olivia

PANORAMIC VIEW OF THE WOMAN'S AUXILIARY TO THE A. M. A. IN FOUR ARTICLES

2. NORTH CENTRAL STATES

Mrs. James Blake

According to the Constitution and By-Laws of the Auxiliary to the American Medical Association the Organization program is carried on by the active work of the Vice-Presidents. Mrs. Southgate Leigh of Norfolk, Va., is first Vice-President and automatically Chairman of Organization. Due to her location on the map, the Second Vice-President finds herself interested in the destinies of the North Central group of states.

Looking backward with pleasant memories to Detroit, and forward with delightful anticipations to Philadelphia, we find this group of states all doing something of common interest.

In the January Journal of the Indiana Medical Society, the Auxiliary President stresses the importance of more constructive work on the part of her organized County groups. "Physicians' wives," she says, in her New Year's address, "hold an enviable position in being privileged to have a part in a world-wide health program, and I would urge every physician's wife to bring before other women *dependable* knowledge, and a just appreciation of the real spirit and purpose and actual achievements of the medical profession." So from Indiana we know we are to have constructive work during this year. Physicians as a class are not prone to participate in legislative matters but when four distinctly separate bills, which affect the profession directly, are presented during one session of a State's Legislature, it is time to be up and doing.

Such is Indiana's situation this year and the doctors of the 7th district have thought it worth while to *instruct* their Auxiliary members on these subjects that their influence may be *properly* used. The Indiana Journal never fails to give the Auxiliary space, and it is little wonder the Indiana women are up and coming, when they have such Editorial Notes to enlighten and guide them in their constructive Program work, as one finds in this same Journal.

Kansas is slowly getting a few things accomplished. A world-wide depression has rendered prophets quite fameless abroad as well as at home, but the Doctor's wife in Kansas is coming into her own, and we prophesy that the Auxiliary will climb to the top due to the indomitable spirit of the leaders in that state.

In Illinois the motto might well read—"Builders we are, and builders we must ever be. Builders, not in stone that shelters life, but builders in life." We find good constructive programs, of well-balanced educational value, we find a Journal ever ready to broadcast Auxiliary news, and best of all we find a healthy Organization line-up, and an Advisory Board from their Medical Society. Several of their County groups are having their members get busy with the "Health Audit Program."

One project of worthy mention comes from Vermillion County on the Eastern boundary of the state. The County Auxiliary put on the Health Institute in Danville last November. A member from every agency in the county working out any kind of a Health program was included in the personnel of the speakers. It was for just one day, but it was worth 365 as a rouser for Auxiliary work. It really was sort of a Christmas Seal Campaign opening, a get-together of Club Women and P. T. A. groups in the County. And what a wise idea for a Medical Auxiliary to have the head lines in the plans for such a "Health Day."

Wisconsin, Iowa and South Dakota are among the latest States to join the National Auxiliary. Organization is the keynote for their work, and the National Study Envelopes are offered as program material. Right now if the modern Doctor's wife needs to get one thing more than another from her organization, it is the knowledge of what is going on in this world; especially the world of Medicine. Women are discriminating more carefully in the clubs they are joining. They are asking what membership will mean to them, what they will get out of it. For that reason the subjects for study should be more carefully chosen, and the roll call should be made to count for something more than jokes and quotations from forgotten poets. It isn't a pleasant feeling for a busy mother who rides miles to a meeting to say when it is all over—"I can't say I know any more now than when I started." And so we find these three states getting themselves established on a firm foundation, with the National program envelopes scattered far and wide to aid and encourage Auxiliary members, already in, and prospective members.

Montana and North Dakota are debating pro-and-con, but as Mrs. Hoxie said in her Detroit report—"I believe it will be a mistake from now on to organize a new state, unless it appears reasonably certain that there is interest enough among the Doctors who want the Auxiliary, so they will foster it and stand back of it." And so we leave Montana half hearted about forming an Auxiliary, and North Dakota in the air.

We find Michigan giving intelligent co-operation with state and county officials. Women, like men, are interested in the improvement of civic affairs and healthful living and are realizing that they need to be armed with a definite knowledge of health laws and public health practices.

Missouri is in a very healthy condition. We find that Mrs. A. B. McGlothan, the President-Elect of the Woman's Auxiliary to the American Medical Association, will attend President Hoover's White House Conference for Child Health and Protection to be held in Washington, D. C., February 19 to 21. Mrs. G. H. Hoxie, the President for last year, will also attend the White House Conference.

Mrs. A. W. McAlester tells us the women of Missouri are finding the Study Envelopes, published by the Education Committee of the Woman's Auxiliary to the American Medical Association, most interesting and instructive. The Studies on "Common Defects in Children," and on "Diphtheria," "Smallpox" and "Typhoid Fever" were recommended by the Department of Health in the Missouri Branch, National Congress of Parents and Teachers, for use on Parent Teacher Programs. Eight hundred copies of each were distributed for use in Parent Teacher Units. Three hundred were requested and supplied for use in Parent Education Classes. Requests are constantly coming in for additional copies of the studies for use by teachers and Parent Teacher Units. The Department of Public Information of the Extension Division of the University of Missouri is including these studies in its suggested programs for clubs in the Missouri Federation of Women's Clubs, and P. T. A. programs. This department requested back numbers of Hygeia for use in such programs. Three hundred copies of Hygeia were supplied by women in the state and by the circulation manager and are being extensively used in club programs. The Missouri Chairman of Public Relations is planning to have a copy of each of the studies "Common Defects in Children," and "Communicable Disease Control," sent to each county school superintendent in the state. Several of the County Auxiliaries are using the study envelopes in their programs.

Mrs. M. P. Overholser of Harrisonville, Mo., has been appointed chairman of Public Relations in the Missouri Auxiliary. This Auxiliary maintains a scholarship for a medical student, per capita quotas being assigned to each county Auxiliary.

They also have sent in 30 per cent of the total number of Hygeia subscriptions recorded from all Auxiliaries from January 1, 1930, to January 1, 1931. Some county Auxiliaries provide Hygeia for all their teachers. Among these are Buchanan, Gentry and Lafayette. Cape Girardeau County Auxiliary has just finished paying a $1,000.00 pledge to a hospital in the city and is now ready for another kind of work. They are a live group and certainly work hard to be able to accomplish so many wonderful worth while things.

Minnesota, the North Star State, has had a busy and successful year on organization. The President and Organization Chairman have visited over the state and planned meetings and Educational programs with many County Groups. In October the International Medical Assembly met in Minneapolis, and at this time the Hennepin County Auxiliary celebrated its twentieth Anniversary, by being hostess for five days to the visiting Doctors' wives. A great many social affairs and an Educational Day, which included a speaker on Public Health, were features. Hennepin County is having a year with a definite program. Each month a speaker is scheduled, and one meeting during the year is reciprocity day and each Auxiliary in the state is invited to send visitors. This group features Philanthropic work for T. B. patients at Glen Lake and does much for the Library at the Sanatorium. They have helped the Medical Society furnish their Library and Club Rooms, spending $1,000.00.

Ramsey County does much the same work. They have a Scholarship Fund for Medical Students. St. Louis County is noted for work in the Public Relations Field. One of the other Counties takes care of a Nurse's Scholarship. The Minnesota Auxiliary has a splendid Advisory Board and a page in the State Journal. The President was one of the speakers on the program for the Annual Conference of Secretaries of the Component Societies of the Minnesota State Medical Association, held in St. Paul the first week in February. This is the first time the Auxiliary has been asked to take part in this Annual affair. Mrs. Hesselgrave spoke on "Uses of the Auxiliary."

And so closing my review of the work of the North Central Group of states may I say again:

Builders we are, and Builders we must ever be
Builders not in stone that shelters life, but
Builders in life itself—ever remembering the future of the world for generations to come depends upon what we *think* and *will* and *do* today.

HENNEPIN COUNTY AUXILIARY

The first regular meeting of the year 1931 was held in the lounge of the Hennepin County Medical Society rooms in the Medical Arts Building, February 18, at 2:30 P. M. Mrs. Martin Nordland, the new president of the auxiliary, was in the chair. She introduced Dr. Stephen H. Baxter, president of the Hennepin County Medical Society, who spoke briefly in appreciation of the services the auxiliary was rendering to the profession and suggested some ways in which the auxiliary can be of definite service to the medical society. He was followed by Dr. J. A. Watson, who discussed the question of medical ethics in a most interesting manner.

Mrs. James Blake presented the need of a Psychopathic Hospital in Minneapolis. The Hennepin County Auxiliary went on record as endorsing this movement. The newly appointed committee chairmen submitted the names of their committee members and outlined their plans for the year. It was decided to give an afternoon card party in the Hennepin County Medical Society rooms the Monday after Easter for the benefit of the Philanthropic Fund, and an evening party in the fall to which the husbands of the members of the auxiliary will be invited.

Plans for the entertainment of the women accompanying the doctors who will come to the State Medical Association in May were discussed. The meeting was followed by a tea and social hour with a musical program of songs given by Mrs. Herbert W. Jones, accompanied by Mrs. J. C. Wilcox.

MEEKER COUNTY AUXILIARY

Meeker County Auxiliary was organized the eleventh of February and voted to affiliate with the state and national associations. Mrs. James Blake, Hopkins, chairman of organization, and Mrs. Hewson, of Stillwater, were guests at the meeting, which was held in Litchfield. Mrs. A. W. Robertson, of Litchfield, was chosen president; Mrs. Brigham, of Watkins, was elected vice president; Mrs. G. A. C. Cutts, of Litchfield, was made secretary and treasurer.

MOWER COUNTY AUXILIARY

A women's auxiliary to the Mower County Medical Society was organized at Austin, the twenty-fourth of February. Mrs. S. S. Hesselgrave, Mrs. Edward Schons, Mrs. Hengstler, officers of the State Auxiliary, motored to Austin to attend the meeting. Mrs. Hesselgrave gave a splendid talk on the national, state and county auxiliaries. An open discussion followed and the group elected Mrs. A. W. Allen, president; Mrs. M. W. Morse, of Le Roy, vice president; Mrs. P. A. Lommen, of Austin, secretary, and Mrs. G. E. Hertel, treasurer.

OLMSTED COUNTY AUXILIARY

A regular business meeting of the Olmsted County Auxiliary was held at the home of Mrs. W. F. Braasch, Rochester, the twelfth of February. Mrs. Hesselgrave, state president, and Mrs. Edward Schons, state corresponding secretary, were guests at this meeting. The auxiliary voted to join the State Women's Auxiliary at this meeting, and is thereby automatically affiliated with the national association. Mrs. J. E. Crewe, retiring president, presided at the business session. Mrs. M. S. Henderson was chosen president to succeed Mrs. Crewe; Mrs. George Steven of Byron was elected vice president; Mrs. F. C. Dolder, of Eyota, was made secretary, and Mrs. G. T. Joyce was made treasurer. The Olmsted County Women's Auxiliary is making its chief activity the cutting of garments for the Red Cross.

ST. LOUIS COUNTY AUXILIARY

The St. Louis County Auxiliary has had an active year under the direction of Mrs. F. N. Knapp, of Duluth. Other officers are first vice president, Mrs. F. F. Slyfield; second vice president, Mrs. F. J. Lepak; secretary, Mrs. T. O. Young; corresponding secretary, Mrs. W. N. Graves; treasurer, Mrs. A. J. Bianco. Food, clothing and toys were distributed to fifty-two families at Christmas. Mrs. Hesselgrave was a guest at the January meeting, at which a Chinese luncheon was served and a play was read by Miss Hoffman. A dance was given in January and the doctors and their wives from Superior were guests.

The auxiliary plans in conjunction with all of its meetings an educational program, such as book reviews, talks by prominent doctors, discussion of public relations. Books have been donated and each member has pledged to earn or donate three or more dollars for the philanthropic work.

RED RIVER VALLEY AUXILIARY

Officers for the Red River Valley Auxiliary are: President, Mrs. W. H. Hollands, Fisher; first vice president, Mrs. Bernard, Thief River Falls; second vice president, Mrs. C. L. Oppegaard, Crookston; secretary, Mrs. O. L. Bertelson, Crookston; treasurer, Mrs. J. F. Norman, Crookston. At the annual meeting in December Mrs. Emil Geist of Minneapolis was a guest of the auxiliary.

RICE COUNTY AUXILIARY

On the evening of February fourth, Dr. and Mrs. J. M. Murdoch entertained the members of the Rice County Medical Society, the auxiliary and nurses at a banquet, followed by music and dances. Dr. Murdoch presided at the business meeting of the medical society. The auxiliary was represented on the program by Mrs. Murdoch, who read a paper on "Health Work Interests." Dr. Schesselman, of Mankato, gave a talk about the meeting of the Southern Minnesota Medical Society, which will be held in Faribault in June. Dr. Horace Newhart, of Minneapolis, gave an illustrated lecture on mastoids. Out-of-town guests were: Dr. and Mrs. Newhart; Dr. Bedie and Dr. Swanson, of Cannon Falls, and Dr. Schesselman, of Mankato.

WASHINGTON COUNTY AUXILIARY

A one o'clock luncheon meeting at Lowell Inn, Stillwater, featured the February meeting of the Washington County Auxiliary. Mrs. John W. Stuhr, president, called the meeting to order. Paul Fesler, superintendent of the University Hospital, gave an illustrated lecture on what the University Hospital is doing for the people of the state.

CONSULTATION BUREAU

(Continued from page 364)

Teacher and Health Education," Hygeia, October, 1930; "How Is Your Child's Health Equipment," Hygeia, November, 1930. An article is to appear in the April number of EVERYBODY'S HEALTH under the division of Health for Teachers and Pupils entitled "New School Health Records Valuable." This is a discussion of the new health record card and its uses. As you probably know, permanent health records of all school children are now required by law, and this article deals in detailed way with the law, its application and possibilities. The Millbank Memorial Fund, quarterly bulletin, July, 1925, deals with rural school health work, and may also be of value to you. By all means read the April number of EVERYBODY'S HEALTH, as this matter is of vital importance to every practicing physician in Minnesota.

PROCEEDINGS OF THE REGIONAL CONFERENCE*

Those present at the Conference were: Mr. Theodore Wiprud, Milwaukee, Wis.; Dr. Otho Fiedler, Sheboygan, President-Elect, Wisconsin State Medical Association; Dr. W. F. Braasch, Rochester, Minn.; Dr. H. W. Skelsey, Secretary, Fargo, N. D.; Mr. J. G. Crownhart, Secretary, Wisc.; Dr. C. B. Wright, Minneapolis, Minn.; Dr. E. A. Meyerding, St. Paul, Minn.; Dr. H. M. Workman, Tracy, Minn.; Dr. W. A. Rohlf, Waverly, Iowa, President; Dr. George Earl, St. Paul, Minn.; Dr. L. Sogge, President, Windom, Minn.; Mr. Vernon Blank, Managing Director, Iowa; Dr. Andrew Carr, President, Minot, N. D.; Dr. O. E. Locken, Crookston, Minn..

AUXILIARY

Dr. George Earl, St. Paul, Chairman of the Committee on Public Health Education, opened the informal discussions of the Conference with a suggestion for a definite, constructive program of coöperation between the women of the State and County Auxiliaries and the organized Medical Profession. Dr. Earl declared that the women are anxious to help and ask only that the medical profession assume definite leadership in their program.

The following plan was drawn up in the discussion that followed:

1. Auxiliaries should be asked not to pass resolutions on any health or medical questions, particularly in legislative matters, without the approval of the Legislative Committee of the State Medical Association. The same course should incidentally be recommended to county medical societies and any other organizations of the medical profession. It was the emphatic sentiment of the group that endorsement of most movements pertaining to health and medical care, to sociological and economic matters, should be confined to the principle involved and not the particular measure proposed.

2. A definite scheme for securing the presence of Auxiliary members on the boards of all lay women's organizations was considered advisable. Such a scheme could be modeled upon the similar plan of the Hennepin County Medical Society.

3. Auxiliaries should be instructed to inform themselves thoroughly about the health and public welfare activities of all women's organizations.

4. They should share with the various branches of organized medicine the obligation to present the truth about health to the public. It is also their responsibility to see that those to whom they delegate this important function, whether medical men or laymen, are qualified for the task.

5. Every county society should have a committee that will actively coöperate with and advise its Auxiliary. Initiative should be developed in each local unit for the work.

SPEAKERS' BUREAU

Public education in matters relating to health should come from the medical profession, members of the Conference agreed. There is a lively public interest in these matters today. If the medical profession does not satisfy it legitimately someone else, less well qualified, will. The task of public health education cannot be delegated to other agencies without loss of medical prestige.

---

*Regional conference of officers of the State Medical Societies of Montana, North and South Dakota, Iowa, Nebraska, Wisconsin and Minnesota, held in St. Paul, February 8, 1931.

Conference members urged practical training in public speaking upon the physicians who are to do this work. They pointed out very definitely that no individual benefits, in their experience, ever came from speaking before lay groups and that the ancient notion that a practising physician may not ethically speak in his own community is out-worn and obsolete.

In the main, talks to the laity by the medical profession should tell what scientific medicine means and what its contribution has been to modern life and modern health protection. It was pointed out that many people in the United States do not, even now, know the difference between the varieties of groups using the designation "Doctor." It is the duty of the medical profession to tell them.

PUBLIC RELATIONS

Dr. O. E. Locken, Mayor of Crookston, pointed to the public relations of the medical society he represents as an example of successful civic functioning of a unit of organized medicine. Physicians have assumed direction and control of public health and sanitation in his community. They inaugurated milk inspection and take the lead in every type of welfare activity. A yearly medical economics meeting is part of his county society's program.

Wisconsin members reported that copies of De Kruif's "The Microbe Hunters" were sent to all members of the Legislature this year through their family physicians.

In these matters, the Conference agreed, it should be the function of the American Medical Association to stimulate the state associations and for the state associations in their turn to stimulate the county societies.

SOCIALIZATION OF MEDICINE

Conference members agreed with Dr. Otho Fiedler of Wisconsin, that Social Medicine is definitely on the way in America. The Medical Profession must be ready for it.

In medicine, as in all branches today, they pointed out, the great problem is distribution. The problem of distribution of medical knowledge increases and becomes more complicated with increasing medical knowledge. In America it is still possible for the medical profession to take the initiative in solving the problem of bringing to the individual the products of medical science at a price the individual is able to pay.

In Europe twenty-three countries have a system of compulsory socialized medicine. Dr. Fiedler said that seventeen have voluntary social medicine. Canada is engaged in socializing its medical service and even in the State of Massachusetts a bill has been introduced into the State Legislature, providing for employment of the medical profession by the state. Current magazines are full of articles on this phase of medical development.

Socialization of medicine in America has interesting and important possibilities in the opinion of the Conference. But the Medical Profession should be ready with a policy or plan when it comes. Conference members felt that the American Medical Association is failing to take proper cognizance of the situation. They felt that every county medical society should be studying the problem.

The following suggestion for acting by the conference was made by Dr. Fiedler: "It is the sense of this body that the question of social medicine is of pressing enough importance to warrant a thorough study and compilation of statistics on the whole question; that every state association should be collecting material which should be available to all who make inquiries on the subject and that a copy of this suggestion be sent to Dr. Olin West, Secretary of the American Medical Association, for his coöperation and assistance in avoiding duplication."

It was the opinion of the conference that every state association should organize a committee also to study the question.

Mr. J. G. Crownhart, Executive Secretary of the Wisconsin Medical Society, suggested that the following material might be helpful.

Some Medical Problems Ahead, W. C. Rappleye, M.D., Director of Study Commission on Medical Education, New Haven, Conn.
Some Problems of Medical Service, W. C. Rappleye, M.D., New Haven, Conn.
Canadian Public Health Journal (outlining the progress of State Medicine in Canada), December, 1930. Toronto.

Current economic problems of the profession in America were grouped for discussion under the following heads:

1. Legislation.
2. Lay Organizations.
3. State Boards of Health.
4. The University Medical Schools.

The Iowa plan for care of the indigent sick by contract between the county medical society and the authorities in charge was discussed with reference to a decision recently handed down by the Supreme Court of California, relative to the practice of a profession by a corporation. By this decision, corporations will be prevented from practice either of medicine or law, in California. Mr. Vernon D. Blank of Des Moines, Iowa, Managing Director of the Iowa State Medical Society, indicated that Iowa county medical societies, who are parties to contracts for the care of the institutionalized sick, might, in the future, sign their contracts individually rather than as a corporation.

Dr. West's attitude toward the growth of contract practice, in that it tends to stimulate a situation which the medical profession should particularly wish to avoid, was mentioned.

The conference agreed, however, that some form of collective bargaining in medicine as in other things was inevitable. The question is now, "Who is to do the bargaining?" Somebody has to negotiate in these matters with insurance companies, industries, legislators. For the good of the public as well as the doctors, the conference believes it should be the medical profession.

There is a tremendous economic waste in America due to poor health and unwholesome sanitary conditions. The first survey of public health to indicate this condition was made in Roosevelt's time, conferees recalled.

It is obviously up to the medical profession to lead in checking this serious economic loss in America, they believe. The State has a right to expect it. The great need today of the medical profession, as well as the public, is medical statesmen to do the job.

Group Insurance was discussed as the logical policy for protection of the individual in any system of contract practice. Such group malpractice insurance is the rule under the Iowa plan.

STATE BOARD OF HEALTH

It was agreed by the Conference that physicians employed in public health work, in state institutions, in state enterprises, railroad corporations, city institutions and in public service, should be required to be members of the County Medical Society of the locality. The presence of members of the State Association on the State Board of Health was thought to be the best means of securing such standards on the part of the hiring groups. It was suggested that influence brought to bear from the State Board of Health is more effective and politic than legislation in such matters.

SCIENTIFIC SOCIETIES

The value of such societies as the Interstate Post Graduate Assembly, the American College of Physicians and the American College of Surgeons was admitted by the conference. It was the sentiment, however, that all of them might better be integral parts of the American Medical Association.

LEGISLATION

North Dakota representatives outlined pending bills before the legislature in North Dakota which include: a Registration Bill, a Hospital Bill (admitting cults), a Basic Science Bill and a Naturopath Bill. In connection with compulsory registration law now pending in North Dakota, the Conference was told that Minnesota is much pleased with its own registration law.

COUNTY SOCIETIES

The American Medical Association is at work on a model constitution for county medical societies. Such a constitution should, in the conferees' opinion, offer considerable help in dealing with difficult problems of expulsion from county medical societies and of dealing with the narcotic traffic.

SUGGESTIONS FOR FUTURE NORTHWEST REGIONAL CONFERENCES

It was agreed that all of the delegates to the American Medical Association from the Northwest states should attend these regional conferences. Such a plan would secure agreement and group action among the Northwest delegates on matters of vital importance.

It was also suggested that a representative from the Bureau of Legal Medicine and the Bureau of Medical Economics of the American Medical Association be invited to attend next year's conference.

Conference groups should be kept small, however, to facilitate informal discussions, it was generally agreed. For the 1932 program it was suggested that three or four problems be selected for particular consideration. Each member of the conference will have an opportunity to make his own suggestions for the choice of problems.

Mr. Crownhart proposed that between meetings, confidential information might, with benefit, be passed around periodically between the states. He suggested that each society be asked to send something on to its fellow societies once a month. For necessary mimeographing and mailing he offered the facilities of his Wisconsin office.

It was decided that the 1932 meeting would be held in the Twin Cities as the most convenient centers to the states involved. Appreciation for this year's entertainment was expressed to Minnesota.

ELECTION OF OFFICERS

Dr. Otho Fiedler, Sheboygan, Wisconsin, President-Elect of the Wisconsin State Medical Society, was elected President of the Conference; Mr. Vernon D. Blank, Des Moines, Iowa, Managing Director of the Iowa State Medical Society, was elected secretary. Dr. Fiedler, as President, is also to act as Chairman of the Program Committee.

PROCEEDINGS OF THE MINNESOTA ACADEMY OF MEDICINE

Meeting of February 11, 1931

The regular monthly meeting of the Minnesota Academy of Medicine was held at the Town and Country Club on Wednesday evening, February 11, 1931. After dinner at 7 o'clock, the meeting was called to order by the President, Dr. J. S. Gilfillan. There were thirty-nine members and one visitor present.

In the absence of the Secretary the minutes of the January meeting were read by Dr. Carl Drake.

Dr. F. R. Wright (Minneapolis) read the following memorial of the life of Dr. F. A. Dunsmoor:

Frederick A. Dunsmoor was born May 28, 1853, in Harmony, a small town later called Richfield, and now a part of Minneapolis. He died on December 16, 1930, at his home in Hollywood, California.

In his death American surgery and this Academy have sustained a grievous loss. His scheme in life was to improve his own qualifications and continuously advance the progress of his profession.

He began the vocation of his choice early in life; at the age of sixteen he entered the office of Doctors Goodrich and Kimball to study mdicine. He acquired his preliminary education in a Minneapolis High School and the University of Minnesota, and pursued his medical education in the Bellevue University and Hospital of New York City. Upon his return to Minneapolis he entered into partnership with Dr. H. H. Kimball, commencing to practice independently in 1877. He was a dominant factor in all of the medical schools which led up to the organization of the Medical Department of our State University.

Dr. Dunsmoor bought the Winslow House and started the Minnesota Hospital College and served as its vice-president and Dean; he was also the Professor of Surgery, and Surgeon to the Dispensary connected with this institution. He aided the Professor of Ophthalmology to establish an Eye, Ear and Nose Clinic which led up to the establishment of the Departments of Ophthalmology and Otolaryngology now existing in our Minnesota State University.

He was one of the founders of the Asbury Hospital and for many years the leading surgeon on the staff. Following this he became associated with the Swedish Hospital. When the Medical Department of the University was organized in 1888 he was appointed to the chair of Clinical and Operative Surgery, which he held until 1913. During the last ten or twelve years of his active career his work was done at St. Barnabas' Hospital. He was one of the pioneer surgeons of Minnesota during the days when native genius and devotion to science were the chief elements that led to success.

In addition to being a constant student, encouraging research, original in thought and technic, a magnetic teacher, and an able clinician, Dr. Dunsmoor was a gifted writer, publishing his articles on his specialties in the leading medical journals of the country. He was keen in debate. He had a flare for picking out the valuable points in papers, to which he listened attentively, thus emphasizing their importance. He did not confine his usefulness to his profession but took a keen interest in civic affairs and the general welfare of the community and thus became an eminent citizen.

Dr. Dunsmoor took an active part in the meetings that resulted in the formation of this Academy. He nominated its first president. The continuous, growing success of this medical society, which its history demonstrates, was greatly aided by his activities in its proceedings.

Early in life he established the habit of taking a vacation each year, during which he would visit the larger hospitals and scientific centers in this country and abroad. One of his chief characteristics was his ability to do an enormous amount of work apparently without fatigue. He was a wonderfully dexterous operator, as hundreds of his devoted students throughout the country will testify. He was a lover of Nature, spending a great deal of his time in the country and in travel. He loved "the spirit of the lakes and the seas and rivers."

His domestic life was delightfully pleasant, as all those who had the privilege of visiting his fine home on Tenth Street in Minneapolis will testify.

In addition to all his virtues was the gift of friendship; fortunate were those who enjoyed it. His wide range of travel and information and well-stored mind rendered his companionship most enjoyable and profitable.

To his two daughters, Mrs. Homer P. Clark, St. Paul, and Mrs. Frederick W. McCartney, Denver; a brother, Dr. John Dunsmoor, Los Angeles; and three nieces in Minneapolis, Mrs. A. W. Armatage, Mrs. Horace Lowry and Mrs. N. H. Scheldrup, we extend our profound sympathy.

(Signed) JOHN F. FULTON, *Chairman*,
EMIL S. GEIST,
FRANKLIN R. WRIGHT,
Committee.

DR. GEORGE N. RUHBERG (St. Paul) read his thesis, entitled "Paresis and Malaria." (To appear in MINNESOTA MEDICINE.)

DISCUSSION

DR. W. H. HENGSTLER (St. Paul): I want to express my appreciation of this fine thesis which Dr. Ruhberg has presented upon a very pertinent subject. I was very much impressed by the emphasis which he placed on the early diagnosis of syphilis, and I want to concur with him in that. I think if more syphilis of the central nervous system were recognized early we would have less need for the malaria treatment. I should like to call attention to the fact that in certain provinces of China (concerning which I had occasion to read in looking up the literature on this subject a few years ago), where malaria predominated among the native population, although syphilis is very prevalent there is positively no neuro-syphilis known. These observations were made by a man named Nathaniel Berkowitz, who was located in China.

Dr. Ruhberg stated that the relationship of malaria to syphilis is not known. I believe that is true. I believe that the mechanism by which the malaria acts upon the syphilis is as yet unknown, but this Chinese situation would indicate that there is some relationship between the prevalence of malaria and the occurrence of syphilis in the blood stream, but not in the cerebrospinal system.

Attention should also be called to examination of the pupils of patients who are suspected of having syphilis. Pupillary fixation to light and accommodation will often give the early diagnosis of cerebrospinal syphilis before any other manifestations are present. The question of the relationship between the clinical symptoms and the serological findings in neurosyphilis, particularly in the patient who has been under treatment and as to whether or not he is cured, is one of importance. At the meeting of the Central Neuropsychiatric Association which was held in Ann Arbor, Michigan, some three or four years ago, Dr. Camp and his associates presented some of their work in neurosyphilis and called attention to the fact that the clinical picture was much more important than the serological findings. If a man obtained a remission, the presence of positive serological tests was not regarded as anything to worry about particularly, as long as the clinical picture remained satisfactory, unless of course the spinal fluid was becoming more actively positive.

Dr. Ruhberg stated that cases of paresis for malarial treatment must be carefully selected. In this I also agree with him. One cannot treat paretics with malaria indiscriminately, because so many of them are so low in vitality and physically depleted that the malaria treatment would kill them; so a proper selection of cases for this type of treatment is of the utmost importance, and no case should be selected who is not physically fit to stand the malaria onslaught. Finally, I believe that it must be conceded by all that the proper place for treatment of paresis with malaria is in an institution. The private practice of neurology, as the ordinary practitioner carries it out, is hardly the place to treat with malaria. In an institution a large number of cases are handled and there the malaria strains can be kept active all of the time and the patients can have the adequate facilities for proper care.

Again I wish to say that Dr. Ruhberg's paper was very fine, and that I appreciated hearing it.

Dr. F. R. Wright (Minneapolis): When one tries to reason out why malaria affects late cases of syphilis he must review those facts which bring about the cure or control of syphilis. A man infected with syphilis produces in the body certain protein substances called antibodies or immuned bodies, the detection of which is called the Wassermann reaction. We treat the patient with salvarsan, mercury or bismuth, but none of these kill spirochetes. When these drugs are introduced into the body, they stimulate the tissues to produce a toxalbumin, which is a stronger spirocheticide than those protein substances produced by nature. When the tissues of our patient become so accustomed to the presence of arsenic, mercury and bismuth that they no longer respond and produce a toxin-albumin, which will destroy the spirochetes, we must find some substance to replace them which will produce a toxalbumin capable of destroying these spirochetes. This we find in malaria. The growth of the plasmodium malariæ in the body produces a certain protein substance which gives a Wassermann reaction. Whether these protein substances produced by malaria are the same as those produced by the presence of syphilis, we do not know, but they undoubtedly are of a similar nature. Is it not possible that these chemical substances produced by the growth of malaria are able to destroy or control the disease even after those substances produced by the presence of spirochete, or by the administration of arsenic, mercury and bismuth have failed?

Dr. E. M. Hammes (St. Paul): Dr. Ruhberg's paper is a very timely one. Any paper that calls attention to the early diagnosis of neurosyphilis is timely, for the earlier we recognize and diagnose these cases the less will be the destructive changes and the more favorable the prognosis.

Syphilographers tell us that syphilis in this country is on the decline. Lida J. Usilton, in a study of the prevalence of venereal disease in the United States, estimates that there are approximately 1,500,000 active cases of venereal disease, out of which about 700,000 are active cases of syphilis. To this must be added the large group of cases which are not under treatment and the still larger group which have positive blood Wassermanns and are asymptomatic.

In about 30 per cent of the cases we obtain a history that the patient has had no knowledge of having had a previous syphilitic infection. In neurosyphilis as a group the blood Wassermann is negative in about 50 per cent of the cases. For that reason the early and thorough spinal fluid study is essential in every suspected case and in every organic neurologic case where the diagnosis is in doubt.

The psychoses associated with syphilis of the brain come under two large groups. The one group comprises vascular syphilis associated with the psychosis. The second group comprises the genuine cases of general paresis. There are many instances in which one is unable to differentiate between the two conditions except that perhaps in the former group the response to antisyphilitic treatment is much more rapid and much more favorable.

We frequently speak of the paretic spinal fluid syndrome, characterized by a moderately high cell count and a 4 plus Wassermann and a typical paretic colloidal gold curve. However, this serological picture does occur in other forms of neurosyphilis. I recall a patient who to my knowledge has had a typical paretic spinal fluid syndrome since 1919, who is perfectly well today except for a dilated pupil and who has never manifested the slightest evidence of paresis.

Malaria undoubtedly is the best recognized treatment for general paresis. It is fraught with a certain amount of danger. According to statistics from the various clinics there is a death rate of approximately 20 per cent directly due to the malarial infection. However, we are dealing with a fatal, degenerative disease and our attitude toward this treatment should be the same as some of the heroic forms of treatment which the surgeon uses in his cancer problems.

Prior to the introduction of the treatment by malaria we were unable to secure a negative spinal fluid in a case of paresis in spite of the fact that we gave these patients thorough and prolonged treatment, both intravenous and intraspinous, for a period of months and months. Since we have been using malaria in our treatment of paretics we not only have had a greater percentage and longer remissions, but have obtained negative serological findings in the spinal fluid in a fairly large group. Sometimes these favorable serological findings do not manifest themselves until months or even a year after the discontinuance of the malarial treatment.

Definite contraindications to malaria are particularly, hypertension, the various forms of nephritis, evidences of myocardial degeneration, and a general devitalized state of the patient. I recall one case of general paresis with a blood pressure of 220/115 in which we gave malaria. With each chill the blood pressure showed a definite drop. After five chills the blood pressure was 85/40 and the patient went into a state of collapse. Quinin was given immediately, intravenously, and various stimulants, and, fortunately, the patient rallied and did not die. The only death we had in our series was in a favorable case from the constitutional standpoint. On the seventh day following the injection of malaria he developed a chill with a temperature of 104°. This temperature did not drop as one usually expects, but continued between 103 and 104 degrees. The patient became unconscious and died within three days. We were unable to obtain a postmortem, but in all probability this patient died from the rare complication where the malaria organism forms multiple thrombi in the smaller cerebral blood vessels and in that way produced a picture of stupor and hyperpyrexia.

Dr. F. R. Wright: That is only about 10 per cent of the estimate of venereal disease ten years ago. In 1896 Professor Taylor of New York wrote a book on venereal diseases in which he estimated about 5,000,000 people in this country had syphilis, or about 1 person out of every 15.

Dr. S. E. Sweitzer (Minneapolis): We have had a small series of patients treated with malaria—sixty or more. We have used it now for about six years and our results have been about the same as the results reported by others. There have been about 30 per cent remissions, that is, placing the patients into occupations or their previous occupations; 35 per cent were benefited and about 35 per cent did not get any benefit. In checking them over, I think the results are in proportion to the degree of deterioration. If we get them early we get better results. There are some things one should do before giving malaria. In the first place the patient should be put into as good condition as possible. I think out of our 60 cases there have been 4 or 5 deaths. First, give them quinin and if they react to quinin do not give them malaria. Then we give them about 8 or 10 chills, but if the patient is not getting along well we interrupt after giving 4 or 5 chills; it is better to interrupt and have a live patient.

Another question is, why do we have paresis? Almost all of it has been somebody's fault. The patient doesn't know, or some doctor has not done his duty by the patient. If these patients are given intensive treatment over a period of three years or more almost none of them will develop paresis, but they often get treatment for a few months or a year and then stop.

Then the use of malaria in cases other than paresis, such as Wassermann fast cases and tabetics. In Vienna they are treating all syphilitics that show signs in the spinal fluid with malaria and they think that prevents neurosyphilis. I think this is a big advance in the treatment of syphilis.

Dr. Hammes: Have we any definite means by which we can determine when the syphilitic is cured, aside from again re-infecting him in order to determine whether he develops another chancre?

Dr. Sweitzer: About 97 per cent of them will not develop nervous syphilis if you can give them treatment over at least three years. Almost invariably the patients we get with nervous involvement have had a few months, often not a year, of treatment. But if you give them at least three years of intensive treatment and then check the spinal fluid, I think you will find that neurosyphilis will practically disappear.

Dr. C. N. Spratt (Minneapolis): I would like to ask two questions: first, how do you give these patients malaria? In 1901, when I was House Officer in Johns Hopkins Hospital, malaria was common; we had a malaria patient in one bed, a typhoid in the next, and a pneumonia in the next; the windows were unscreened, so there was opportunity for getting malaria. Where do you now get the malaria organisms, especially in Minnesota, to give to these patients?

Second, I wonder if anything has been done along this line with foreign protein, or low or high frequency current, and diathermy.

Dr. Ruhberg (in closing): I wish to thank the gentlemen for their very kind discussion of my paper. I did not include any of the cases of frank paresis in this paper for the reason that it is practically conceded the world over that malaria at present is the best treatment for paresis and it would be merely a repetition. I included only those patients in which one could not make a clinical diagnosis of paresis, but who are in danger of later developing paresis or tabes. Personally, I feel that a person with negative spinal fluid, who has had syphilis, has a very good chance of not developing a parenchymatous neurosyphilis. I would not be willing to state that such a person who has a negative spinal fluid will never develop neurosyphilis.

If we are going to do the right thing by our patients it is necessary that we discover the presence of a neurosyphilis early and treat it until all serological signs disappear. In the severe cases, such as described by Moore in his Class 3, or pre-paretic type, it will be found that malaria is often needed to bring about this result. We have all had experience in treating late cases of paresis in which the patient may have been saved and a negative spinal fluid finally obtained, but so much parenchymatous destruction had taken place that the treatment merely improved the patient to the level of a high-grade imbecile, or placed him in the feeble-minded class, and as a result has caused great distress to the family in handling and taking care of him. In these cases the treatment certainly could not be classed as successful, and in many cases it would have been better not to have given malaria at all.

In answer to Dr. Spratt's question, we draw 10 c.c. of blood from the vein, and treat it with citrate to prevent coagulation, and then keep it warm until we are ready to re-inoculate. Four c.c. of this citrated blood is given intravenously, and as a rule would begin to cause a rise in temperature in 7 to 10 days. I purposely did not mention typhoid in the treatment of paresis, but include that in the reasonable treatment that could be given before malaria. There is no question but that typhoid is safer and is very valuable. Some claim that it is as good as malaria. However, it has not had the world-wide recognition that malaria has in obtaining the lasting and satisfactory remissions. Fever may be the major factor in the treatment by malaria, and diathermy is being used in an experimental way, and the few reports are enthusiastic.

Dr. Hammes' estimate that 20 per cent of these patients die of malaria is rather high, I believe. The usual statistics I have read give the mortality as around 10 per cent, and it must be remembered that these cases include patients with frank clinical paresis who have already deteriorated to a more or less extent, and are for the most part confined to the asylums. In well selected pre-paretic or asymptomatic cases showing the paretic formula, I believe malaria would show a very marked decrease in mortality. For those cases in which malaria is objected to on account of high blood-pressure, vascular conditions, kidney trouble, etc., typhoid vaccine would be a better choice of treatment.

Dr. A. N. Collins (Duluth) reported the following case:

The case I wish to present is rare in my experience. This man first came under the observation of Dr. S. H. Boyer, who referred the patient to me for surgical treatment. The man was forty years of age and of Swedish descent. He complained of

1. Loss of appetite.
2. Pain in the pit of the stomach, at first right after taking food and later constant.
3. Vomiting, which he stated came with the pain or soon after the pain started.
4. Loss of weight—about 15 pounds.
5. Weakness.

The stomach content (33 c.c.) contained a small amount of mucus and much undigested material; free HCl, 0; total acid 8.20. At the second examination it was about the same. On January 22, 18 hours after taking food, only about 5 c.c. were recovered, which consisted of gelatinous food particles. His weight on January 16th was 116 pounds; on January 21st was 121 pounds. X-ray examination showed 6-hour residue and 20 hours afterward there was still some barium in the stomach; the bulk of the meal was in the large intestine and the tail of the meal in the transverse colon.

The condition was regarded as early cancerous obstruction of the pylorus and was referred to me for exploration. A note was made by the clinician that early cancer of the pylorus was probable.

On exploration I found a tumor which was not nodular. I called the attention of my assistant to the fact that one could press the finger down into what appeared to be a depression. It seemed that instead of cancer we had a deep indurated ulcer. There were several glands near the pylorus which were round and not nodular or hard. There was no nodular involvement of the liver. There was a shower of stippling over the pyloric area. I did a resection by the posterior Polya method. The pathologist reported that there was an abscess in the wall. This specimen shows a cavity which is a submucous abscess; it contained about one-half dram of pus. (Specimen shown.)

DISCUSSION

Dr. Arnold Schwyzer: This is an unusual case. I have never seen one in my own work, but in the literature up to a few years ago I know there were some over two hundred cases on record. The abscess is between the submucosa and the muscularis and may go somewhat into the layers of the muscular coat. Most of the cases, however, which I have in my memory were treated by drainage and walling off. That a resection could be done in Dr. Collins' case was quite a fortunate thing. There were a good number of deaths after draining operations. Resection, when it can be done cleanly, in other words, when the process is not too far spread, is surely preferable.

Dr. A. E. Benjamin (Minneapolis): I would like to ask Dr. Collins if microscopic examinations were made to see if a diverticulum is present. It is possible to have a diverticulum from the stomach and then an infection and abscess, the opening having closed up.

Dr. Collins: There was no malignancy and it does not penetrate the wall exteriorly. There was only a slight suggestion of a peptic ulcer of the mucosa about ⅛ of an inch in diameter which is not open at the present time. It is possible that there was a small peptic ulcer as the original cause, and that it healed over superficially.

Dr. Arnold Schwyzer: I think in the literature hardly any case is known to have been due to diverticula. It was always thought that the condition was due to either a hematogenous infection or perhaps in some cases to a small puncturing trauma.

Dr. Arnold Schwyzer (St. Paul) reported the following case:

About a month ago I was asked to see a case with another surgeon—a large tumor of the abdomen which had the contour and relations to the cervix of a fibroid. The patient was a young woman twenty-two years of age. She claimed she had menstruated regularly and that the tumor would at times be very large and then again would practically disappear. When I examined her this tumor reached to the middle between the symphysis and filled the upper part of the pelvis tightly. The cervix was hard and virginal. The supravaginal portion of the cervix ran far backward and upward. From the cervix one could feel a gradual and unbroken transition to the tumor. This was felt as well on both sides as in front. But the tumor fluctuated, perhaps somewhat tensely, but definitely. Could it be perhaps a cystic tumor of the ovary which was plastered onto the corpus uteri by some inflammatory process? There was no trace of pain. Could it be a cystic tumor of the corpus uteri, a cystic degeneration of a fibroid? A hydro- or hemato-metra was excluded by the regular menstruation which was not to be questioned.

I was absent when the operation was performed, but the two surgeons who operated found a very perplexing and disquieting condition which appeared to be pregnancy. The tumor was the uterus; it was soft and fluctuating, of a bluish hue, and the adnexa started off symmetrically on either side. When a carefully inserted needle yielded clear fluid, the diagnosis seemed to be definitely forbidding an aggressive procedure and the abdomen was closed. "Primum non nocere" is a valuable principle. No particular harm was done and no bridges were burnt. But a lingering doubt had remained in the surgeon's mind, I am sure, for when on my return I definitely rejected the diagnosis of pregnancy, he readily assented to the proposition to re-operate and to enucleate the tumor, which must be a hydropically degenerated fibroid. While the uterus was the size of the five months' pregnancy, the external genitalia were entirely normal, the cervix small, hard and virginal. The change in size of the tumor was so far unexplainable. Was it an error of observation on the part of the patient? Inquiry in the laboratory as to the amount of albumin found in the withdrawn fluid showed that a large amount of albumin had been noticed. Amniotic fluid contains only an insignificant trace—hardly any. Thus the diagnosis "hydropic degeneration of a fibroid" was confirmed.

This morning we re-operated. The tumor was about the size it had been judged to be at my first examination, but both surgeons who had performed the first operation at once declared that at the first operation the tumor had reached much farther up. It was plainly fluctuating. The color was normal for a fibroid uterus; there was no bluish hue. We shall try to explain this difference later. The adnexa left the uterus on each side at the same level, but this level was too low for a pregnant uterus. The tubes emerged at the junction of lower and middle thirds, and abnormally far in front. The fibroid was therefore in the upper posterior wall of the uterus, though the whole was apparently a uniformly enlarged womb. In this area also the fluctuation was the most outspoken. All this became only definitely clear after the mass had been delivered from the pelvis, which was, however, not a simple matter. The tumor was partly in the pelvis and filled it so completely that it was impossible to insert the fingers far enough into the pelvis to bring the tumor up. With the help of probangs on both adnexa it was gradually worked out of the small pelvis. The fluctuation made us avoid toothed Museux forceps or a corkscrew tractor. After bringing the uterus into the wound a transverse incision was made over the upper posterior surface and the fibroid was shelled out. Twice during this process the finger slipped into a cavity and clear fluid escaped. After the enucleation was completed the mass was still about the size of a grapefruit. It was a practically necrotic and very hydropic intramural fibroid with large irregular cavities of disintegration. From the torn area the inner parts of the tumor bulged out as a flabby, white, bloodless and exceedingly soft material.

What had puzzled the surgeons before was the fact that the tumor, according to the definite statement of the patient, had become very large and prominent and then again had practically disappeared. On the two occasions when I had seen her, the tumor was about the same size. At the operation this morning it struck me that possibly or rather very probably this difference was to be explained by a change of the position of the mass. When the bladder and the ampulla recti were perhaps abnormally full, the tumor was forced up into the large pelvis and on account of its size would stay there. It then bulged greatly. When these viscera were empty the abdominal pressure could sometimes, under unfavorable conditions, push it back into the small pelvis and thus the tumor seemed to have disappeared almost completely. The snugness with which it fitted into the pelvis rim made this explanation probable. The fibroid fitted like a cork in a bottle. This snugness in fitting into the pelvic rim seems to me also to explain possibly the difference (as emphatically stated) in the appearance of the color of the uterus at the two operations, inasmuch as perhaps the marked stretching of the uterine vessels when the tumor was high in the abdomen would cause some degree of cyanosis.

The drawback of having to undergo two operations was compensated by having the pelvic organs preserved intact. Not removing any of the exuberant musculature of the tumor bed and broadly uniting the surface with four layers of continuous suture left a somewhat unsightly shape for the uterus, but gave us good assurance against rupture in a possible future pregnancy. Furthermore, this deformity, due to the bulky capsule of the tumor, will in all probability correct itself gradually, and at any rate has no importance. The uterine cavity had not been entered.

DISCUSSION

Dr. W. H. Condit (Minneapolis): The history of Dr. Schwyzer's report of a patient is of unusual interest to me because it almost parallels a patient I operated upon at the University Hospital several years ago, the exception being that this patient's tumor was the size of a full term pregnancy.

It was at the time when Dr. Beebe was with us, and he happened to be in the operating room at the time. After opening the abdomen and exposing the tumor, his remark was, "Young man, I have seen better men than you obliged to leave the state for taking out a uterus like that." The serosa was bluish and injected. There was fluid underneath, and was a picture of a full term pregnant uterus. On palpation one could almost feel elbows, knees and even the head.

I ruled out pregnancy practically the same way Dr. Schwyzer made his diagnosis in his case—that is by palpating the cervix from the abdominal cavity, finding a firm, hard, contracted cervix, a condition impossible in pregnancy, especially full term.

The tumor was removed. On opening, a large amount of fluid was evacuated out of a thin-walled cavity. On further incision of the tumor, another cavity with fluid was found. In the wall of this cavity were several hard myomata, which were the "elbows" and "knees" supposedly felt. On further resection, a large, hard myoma the size of an infant's head was found.

This patient was much older than Dr. Schwyzer's patient, one point which assisted in ruling out pregnancy, although she was not absolutely beyond the age of conception.

Dr. C. B. Wright (Minneapolis) reported the following case of Undulant Fever:

The patient was a male, aged 47, single. His mother was living and well; father died of Bright's disease; and one brother and one sister were living and well. He had been in the dairy business since he was a boy, except from 1912 to 1919, when he was in the elevator business.

He had always been a fleshy man. In 1908 he first had rheumatic fever and then had it every year for 5 years. The attacks lasted about 5 weeks. Temperature would go up to 103°. He would be lame and could not walk for a long time after attacks and his feet pained a great deal. In 1920 he had an attack of severe pain in his back and right side which the doctor said was due to liver trouble.

He was first seen early in 1927. He was having a lot of dull aching pain in his left ear, took cold easily, and had a raw throat and used to have a lot of phlegm back of his tongue. He stated that he had never had pneumonia nor pleurisy nor typhoid. He complained of more or less indefinite trouble with his stomach; vomited easily in the presence of bad odors or if he sees something unpleasant. The most he ever weighed was 245 pounds, and his weight varied from 220 to 200 for the last four or five years. The last four years he had a tendency to drowsiness and could go to sleep anywhere. He said he was a small eater, but ate everything. His blood pressure had varied from 143/75 to 110/70. He chewed tobacco and smoked, but used no liquor.

On examination the patient was found to be rather fleshy, with pendulous abdomen. The reflexes were normal; no tremor, no eye signs. The throat and teeth were normal. The neck was large, with slight enlargement of the thyroid. Lungs and heart were normal. Liver and spleen were not palpable. The rectal examination was negative.

On July 5, 1927, he came back, having an attack of pain in the right side under his ribs; also some pain on the left side. He was dizzy, feverish and nauseated. He had never been jaundiced, and had no diarrhea. He was tender over the gallbladder area but there was no tenderness over the back. The upper right rectus muscle was somewhat rigid. This attack lasted only a short time. He also complained of numbness in his fingers and said that at times his feet had swelled.

On July 27, 1930, he was seen by Dr. Adam Smith during my absence from the city, when he complained of severe pain in the left hip radiating almost to the knee. Dr. Smith felt it was neuritis. He also complained of back pains.

On February 6, 1931, he came in again complaining of general bad feelings, no pep, drowsiness, stating that he thought he had been feverish for some time. In fact, he had been taking his temperature for two or three weeks and found he had some fever every day. On examination his temperature was found to be 101°. The throat was not inflamed and there was no evidence of a cold. The lungs and heart were negative. There was no rash, no glandular enlargement, and no edema. Abdominal examination was negative. The blood Wassermann was negative.

There being no obvious reason for the fever, I had some blood sent to the University and the report came back positive agglutination in a dilution of 1:320 for bacillus abortus. Typhoid and paratyphoid were negative.

He came back on February 10, 1931. His temperature was 100.4° about 4 P. M. Blood count—Hb. 86 per cent; r.b.c. 4,140,000; w.b.c. 8,050. Differential: polys. 44 per cent; lympho. 53 per cent; monocytes 1 per cent; basophiles 2 per cent; eosin. 0.

On going back over his records, he says that in 1900 he took care of a herd of fifty cows and that about one-third of the herd aborted. In 1901 they raised only three calves from the fifty. During the last four years there had been abortion every year in his herd. Last winter there were 2 abortions in 5 cows. The herd was tested for tuberculosis but not for undulant fever. He thinks he has had the infection for at least four years, and has had the same trouble at intervals since he was a boy. He also claims that the man working with him on the farm complains of the same symptoms. Because of the continuous contact with cows, it is difficult to say how long this disease has been present. Another interesting feature of this case is the history of attacks of inflammation which suggests gallbladder disease.

Dr. Reuben Johnson recently reported, at the Abbott Hospital Staff meeting, a case where no agglutination was found but the organism was isolated from the urine and definitely proven to be B. abortus. He also reported that Dr. Amoss, of Duke University, who had a case of undulant fever with gallbladder trouble operated upon and found the bacillus in the gallbladder. The organism has also been isolated in stools. Cases have been reported where agglutination never was present and the only way to make a definite diagnosis was by isolation from the stools or urine. In Oxford Medicine there is a very excellent account of this disease, with a bibliography down to July, 1930.

DISCUSSION

DR. HAMMES: What is the treatment of this condition?

DR. COLLINS: I would like to ask two questions: first, how does this organism affect experimental animals; and, second, what is the mode of transmission —in the secretions, food, or what?

DR. WRIGHT: There apparently is no particular treatment for this mild type of infection. Gradually it burns itself out in varying lengths of time. The length of time an individual may harbor this infection is not definitely known. Cases have been reported lasting as long as four years.

In reply to Dr. Collins, if this organism is injected it produces a bacteremia. This undoubtedly also happens if animals are fed infected material. The mode of transmission in animals is generally thought to be through swallowing infected material. It may be directly transmitted from one animal to another through the blood stream. This, of course, does not happen to any extent. Workers in slaughter houses have been directly infected through abrasions. The mode of infection in this part of the country, in human beings, is considered to be by mouth and largely through the drinking of milk.

The meeting adjourned.

R. T. LaVake, M.D.,
Secretary.

THERAPEUTIC POSSIBILITIES OF GASTRIC MUCIN

The gastric mucus aids in protecting the cells from digestive or "erosive" damage by the acid that is poured into the lumen of the stomach when the gastric glands are active. Undue secretion of mucus in the stomach is responsible for lowering of the gastric acidity, just as proteins tend to "bind" free hydrochloric acid. The actual capacity of mucus to produce such an effect has been verified. Mucin prepared from hogs' stomachs was more potent than equivalent amounts of common protein foods such as gelatin, meat and egg white. In a few human patients with definite histories of ulcer and roentgenographic evidence of peptic ulcer the addition of powdered mucin to the ordinary bland diet brought about relief from subjective symptoms. (Jour. A. M. A., February 28, 1931, p. 693.)

PROCEEDINGS OF THE MINNEAPOLIS SURGICAL SOCIETY

Meeting of February 5, 1931

The Annual Banquet of the Minneapolis Surgical Society was held at the Nicollet Hotel on the evening of February 5. The President, Dr. A. T. Mann, presided and introduced the guest of honor and speaker, Dr. Clay Ray Murray, Associate Professor of Surgery at Columbia University. The title of Dr. Murray's address was "Delay and Non-union of Fractures." There were 36 members and 44 guests present.

During Dr. Murray's visit in the city he gave a talk before the Hennepin County Medical Society on "The Proper Use of Physiotherapy in the Treatment of Fractures," and also presented his "talkie" on "The Treatment of Angle Fractures."

On Thursday morning Dr. Murray conducted a Clinic on Fractures at the General Hospital, which was of unusual importance in view of the fact that Dr. Murray discussed the actual treatment of the cases at hand. On Thursday afternoon he addressed the medical students of the University in the Anatomy Amphitheater, speaking on the "Modern Conception of Bone Formation in the Adult and its Bearing on the Clinical Treatment of Fractures." These meetings were open to the general profession, and were unusually well attended, and the talks received with much enthusiasm.

The formal banquet meeting at the Nicollet Hotel was for the members of the Surgical Society and their invited guests. In addition to the paper, Dr. Murray told of their work, both experimental and clinical, at the Presbyterian Hospital in New York City, and, in closing, extended a cordial invitation to any of the physicians who came to or near New York City to come to the hospital and observe the work that is being done there.

H. O. McPheeters, M.D., *Secretary.*

PARIOGEN TABLETS

There has grown up, during the past four or five years, a huge business in the sale of antiseptics and germicides, real or alleged, that are frankly purchased, if not obviously sold, for contraceptive purposes. The term contraceptive is not used in the advertisements; "feminine hygiene" takes its place. "Pariogen Tablets," marketed by American Drug and Chemical Company, of Minneapolis, have been advertised as the "new mode of personal hygiene." An advertisement stated "Pariogen Tablets may be carried anywhere in a purse, making hygenic measures possible almost anywhere, no other accessories or water being required." The advertising has stressed that the tablets are non-poisonous, but do not declare the composition of the tablets. Some six years ago a reading notice appeared in a medical journal from which it appears that the tablets are essentially tablets of chloramine, U.S.P. By selling these under a proprietary name as a nostrum of essentially secret composition, the company is able to get a price that is out of all proportion to the value of its product. (Jour. A. M. A., February 7, 1931, p. 458.)

PROCEEDINGS OF THE MINNEAPOLIS CLINICAL CLUB

Meeting of January 8, 1931

The regular monthly meeting of the Minneapolis Clinical Club was held in the lounge of the Hennepin County Medical Society on Thursday evening, January 8, 1931. The meeting was called to order at 7 o'clock by the President, Dr. Moses Barron. There were 25 members and one visitor present.

Minutes of the December meeting were read and approved.

The President called the attention of the members to the new magazine rack in the Library room which had been presented by the Clinical Club to the Hennepin County Medical Society.

The scientific program was as follows:

Dr. Walter E. Camp reported two cases of Melanotic Tumors of the Eye.

I wish to present two cases of intraocular malignant melanomata in which rather complete pathological examinations were made.

(a) The first case is that of a married woman, aged 54 years, who came for examination because of intermittent redness and pain in her right eye which had been blind for some years. There was no history of injury or serious illness. Examination showed conjunctival and ciliary injection; the anterior chamber was completely obliterated; the iris was atrophic and pushed forward against the cornea. The pupil was eccentric, irregular and fixed. The lens was cataractous, preventing examination of the fundus. The eyeball was stony hard, and tension with the tonometer was 60 mm. Hg. as compared to 20 mm. Hg. in the left eye. There was no light perception present. Transillumination of the globe showed the outer half to be opaque.

The general physical examination showed numerous small, hard, bluish, subcutaneous tumors on the scalp, chest, abdomen, axillæ and groins. The liver was not enlarged. There was no weight loss, and no cough. The patient stated that the subcutaneous nodules came about two months previous to the time of examination.

A diagnosis of malignant intraocular melanoma was made, and enucleation done. A biopsy also was made from one of the subcutaneous tumors.

The eyeball on section showed a large melanotic tumor involving about three-fourths of the choroid and extending into the ciliary body. Perforation through the sclera had occurred at the equator along the vortex veins. Parts of the tumor were deeply pigmented; others necrotic and showing cholesterin crystals.

There was no local recurrence of the tumor after enucleation, but the metastatic tumors increased in size and the liver became enlarged. Death occurred fifteen months after enucleation. Autopsy showed generalized melanomatosis of all organs and visceral surfaces.

(b) The second case is one that I saw some years ago with Dr. Murray at the University Hospital. The patient was a young farmer nineteen years old who came complaining of loss of vision in the left eye. His parents noticed a change of color in the iris of this eye almost two years before coming to the hospital.

Examination showed a mild conjunctival and ciliary injection. The pupil was dilated, the anterior chamber shallow. The iris showed areas of deep pigmentation scattered from the periphery to the pupillary margin. These areas were not raised above the surface. The lens was clear. The fundus showed glaucomatous cupping of the optic disc and optic atrophy.

Enucleation was done and the whole eyeball sectioned serially. Microscopically the entire circumference of the iris was found to be infiltrated with a diffusely pigmented tumor. Graphic reconstruction showed the tumor as outlined in the slide. (Slide shown.) The tumor was composed of round and spindle cells, many of which were deeply pigmented. The tumor cells were most numerous at the periphery of the iris, and extended into the ciliary body and onto the posterior surface of the cornea. Some of the tumor cells were found extending out along the anterior ciliary veins. Aside from the glaucomatous cupping of the disc and optic nerve atrophy, the remainder of the eyeball was normal.

Annular malignant melanoma of the iris or ciliary body is exceedingly rare. They are slow growing and may give late visceral metastases similar to choroidal melanomata.

DISCUSSION

Dr. Erling Hansen: These two cases are very interesting and demonstrate, at least to some extent, the difficulty one finds in making a diagnosis. In the first case if it had not been for the fact that metastases were found throughout the skin in places where nodules could be taken out and sectioned, the diagnosis would have been rather difficult. The fact that the lens in many of these becomes sclerosed and cataractous makes it difficult or impossible to see the fundus, so that the presence of tumors cannot be diagnosed.

In the old division in stages of development of tumors, particularly tumors of the choroid of which we have the greater number in the sarcomatous group, the first stage—the quiescent development of the tumor—was missed as the patient is seldom seen in this stage. Most patients come to the oculist because of some disturbance of vision or pain, and unless the tumor is in the macular area there is very little early disturbance of vision. Then the tension in the eyeball increases and brings on the second stage, in which probably most of the patients are seen. The third stage is the breaking down of the tumor; and the fourth stage, the invasion of other tissues.

Unfortunately, one of the sad things about these tumors is that they metastasize very early, especially in the liver, and even though the eye is enucleated at a very early stage, the metastasis has already taken place.

Another thing causing difficulty in diagnosis is in extensive detachment of the retina. The evidence of a solid tumor behind the retina is suspected and it can often be demonstrated in the anterior half of the eye by transillumination through the sclera. If the tumor mass is more posteriorly situated we have more difficulty.

I was particularly glad to see the reconstructed section of this annular tumor, which is rather a rare condition.

Dr. Kenneth Phelps: There is only one thing I might add, and that is in my experience I have known of only one patient who had his eye enucleated for a melanoma and did not have a metastasis. The operation was done about 30 years ago and the patient still lives.

Dr. Moses Barron: I would like to ask Dr. Camp why the eye was enucleated in the first case after there were obvious metastases throughout the body?

Dr. Camp: That was done for the relief of pain and also to confirm the diagnosis. I might add that the last case, the one I saw with Dr. Murray, was reported in full by him in the *American Journal of Ophthalmology.*

Dr. J. S. McCartney: The whole subject of melanoma is a very interesting field in tumor diagnosis because of the great variety of histologic pictures one may see in connection with these tumors, whether they are in the eye, or skin, or intestinal tract. One can get almost any sort of a microscopic appearance and if one reviews a series of these he sees why there is so much disagreement in the naming of a melanoma; why one person wants to call them melanosarcoma and another melanocarcinoma. You may see everything from a spindle cell to round cell, or alveolar sarcoma, and even to things that you want to call carcinoma. Occasionally you see one which you want to call giant-cell sarcoma. I saw such a one not very long ago which was in the small intestine as a primary tumor about 10 or 12 inches from the ileocecal valve. It was 10 by 2 cm. and ulcerated but not an annular tumor and, in spite of its size, did not produce obstruction. The patient was operated for appendicitis, which she had.

Several years ago a patient came to the University Hospital with an enlarged liver. There were several diagnoses made in the hospital and when she died the enlarged liver was found to be the site of metastatic melanoma. Then they got to looking around and found that she had had an eye removed. In looking up her history it was found that she had been in the hospital about five years before when the eye was removed for malignant melanoma.

Another case I recall, which was reported by Dr. Morrison, of a patient at the General Hospital considered as some functional neurosis. It was found that she had a melanoma in the brain and another in the small intestine and they could not determine which was the primary tumor.

Dr. Barron: The case which Dr. McCartney mentions was very interesting. I remember it very well because I was house officer at the hospital at that time. A number of different diagnoses were made on the case. At autopsy an enormous liver was found containing large black tumors. It was then decided to look up the original record of the enucleated eye which had been removed by Dr. Todd about six years previous. This was found to contain melanosarcoma.

Dr. H. L. Ulrich: They have learned a lesson over at the hospital now. They have had one similar case since in which the condition was diagnosed.

Dr. T. A. Peppard read a case report for Differential Diagnosis: Hemoptysis with Gradual Development of Pulmonary Lesions.

The patient was a female, aged forty-one, office worker, who was first seen in September, 1930. Her complaints at that time related entirely to the gastrointestinal tract. She stated that she had had a "summer cold" for three months during the past summer, expectorating some mucous material in the morning. She had never expectorated any blood. She became slightly dyspneic when excited. She complained of some transient pains over the anterior chest.

Her family history is quite unimportant. There was no exposure to tuberculosis at any time. She stated she had had tonsillitis and had been observed by a rhinologist who had suspected the possibility of some sinus trouble.

The patient was well-developed, and moderately well-nourished, although thirteen pounds under her best previous weight. Pulse rate was between 80 and 90; temperature between 99° and 100°. There were some crowned and filled teeth noted, although her dentist reported that all the teeth were vital. The tonsils are not greatly enlarged, but, because of the previous history of tonsillitis and also because of the presence of a number of cervical slightly enlarged lymph nodes, I considered that the tonsils might be a focus of infection. The thyroid was normal in size. The heart was quite normal; blood pressure 110/80. There were no physical signs indicative of lung disease. There was no enlargement of any of the abdominal organs, although the patient was diffusely tender to palpation over the abdomen. No pelvic disease or abnormality was found.

Examinations of blood, urine, stools, and stomach contents were quite normal. Roentgen examination of the gastrointestinal tract showed no evidence of any organic disease. The skin tuberculin test was definitely positive, and stereoscopic plates of the chest showed only calcified lymph nodes at the left hilum. There was no eviednce of tuberculosis or other parenchymal pathology.

On November 13, without other symptoms, the patient expectorated about one tablespoonful of blood, and from that time until the present (January 8, 1931) she has raised some material containing some amounts of blood almost daily. Since then numerous specimens of sputum have been examined. These all have been small in amount, the 24-hour quantity not being over 30 c.c. at any time. The sputum has consisted of grayish, greenish purulent material, mixed with red blood in streaks, and with some clots. No tubercle bacilli have been found at any time, but there have been many other organisms—staphylococci, diplococci, and streptococci. There was no characteristic odor to the sputum.

Physical examination November 20th showed a slight impairment of resonance over the lower half of the left chest posteriorly, with a slight change in breath tones, they being broncho-vesicular in character. Stereoscopic X-ray films were made on this date. Calcified glands in the region of the left hilum were again shown as before. There was no evidence of parenchymal pathology in the upper portions of either lung. There was slight circumscribed density in the lower left lobe.

For a month's time the patient continued to have sputum with blood, as mentioned before, but for the past three weeks the purulent character has disappeared. The physical signs in the lower left chest have cleared up. The patient has gained nine pounds in weight, and feels quite well.

The X-ray examination of the chest was repeated January 3rd, 1931, and these plates show now a definite resolution of the localized infiltration, previously shown. In the opinion of the roentgenologist there is no evidence of tuberculosis.

I do not believe that this patient has pulmonary tuberculosis. There is no evidence at this time that she has a primary new growth of the lung. I have thought of the condition as being one of those non-specific pulmonary infections similar to those described under various titles by Reisman, Miller, Hamman, and Wolman. I have had several cases similar to this, but I do not recall any in which there has been hemoptysis, although some of these other observers have recorded this symptom. They are most often associated with, or dependent upon, chronic infections of the upper air passages, particularly the sinuses and tonsils, and in the present case I have advised that the patient have a tonsillectomy.

DISCUSSION

Dr. F. W. Wittich: I would like to ask Dr. Peppard more in detail about the sputum. Aside from the X-ray, which is sometimes misleading in these basal lesions, the positive cutaneous test could be followed up with the subcutaneous test, starting with ½ mg. of tuberculin, to see how much of a constitutional reaction resulted, and if allergic to comparatively small doses. Then I think a 24-hour specimen of the sputum would have given us leading information. Pottenger has long ago pointed out the sediment volume determination and albumin content of the sputum as being valuable in differentiating pulmonary tuberculosis from simple catarrhal and non-tuberculous abscess.

Dr. Peppard: All of the specimens that I received had blood in them. The quantity was not large at any time. I should estimate that she probably did not raise at any time over a tablespoonful in 24 hours.

Dr. Wittich: Even so, I think that searching carefully for elastic fibers might give us some information. In their absence, of course, I would feel there was less chance of pulmonary suppuration. The fact that the apices are entirely clear and that the lesion is basal is evidence against a tuberculous lesion, although there is some evidence of childhood tuberculosis on the left side as shown by the calcified hilus nodule. I think perhaps one would consider malignancy until he had seen the X-ray. It certainly is a favorite site for primary carcinoma, but the shadow does not have that appearance and the patient is gaining in weight. Then there is a group of cases that we are seeing right now with ordinary colds, with infected tonsils, sinuses, or some other focus of infection where there is a patch of lower lobe consolidation with or without bloody sputum. There are at times small areas over which a shower of very fine crepitant râles are heard and may persist for weeks. Occasionally there develops in these areas of unresolved bronchopneumonia a small abscess which clears up in six to eight weeks, showing no more of a shadow than this and subsequently clearing up entirely.

The evidence presented, I think, points toward a small abscess which is resolving and one arising from some other source. I would diagnose this case of Dr. Peppard's as non-tuberculous, inflammatory in character, resulting in a small pulmonary suppuration, probably metastatic; and if it does not clear up in a reasonable length of time one might suspect malignancy.

Dr. H. L. Ulrich: I think Dr. Wittich has covered the field very well. I might suggest a localized bronchiectasis, but that is the only thing which I could add to this discussion.

Dr. R. G. Allison: I have not seen these plates before, and do not think there is much difference in the three; if so, the one of November possibly shows a little more of the inflammatory condition. Clinically it might be a bronchopneumonia, but from the history I think she has a small abscess there. Certainly there is nothing to suggest a primary new growth. It would be unusual for it to be tuberculosis. I think one can rule out bronchiectasis, tuberculosis and tumor.

I think most likely it is a metastatic abscess which may flare up again but which in the end will probably undergo complete resolution.

Dr. J. C. Michael gave a lantern slide talk on "Schematic Orientation for Pathogenesis, Localization and Classification in Neuro-Psychiatry."

DISCUSSION

Dr. H. B. Hannah: As far as the classification is concerned, this was very well done by Dr. Michael. There is one thing I might add and that is I am always hoping the time will come when we shall know more about the physiology involved in this question and not so much about descriptive psychiatry.

The meeting adjourned.

H. Bright Dornblaser, M.D.,
Secretary.

LIMITATIONS OF BACTERIOPHAGE THERAPY

Recent investigations suggest that future therapy with bacteriophage preparations must be limited to certain definite anatomic types of infection. The deductions drawn are that no therapeutic effects whatever are predictable for bacteriophage except under conditions in which local extrabacterial bacteriophage concentration can be raised and maintained. From this it appears that bacteriophage therapy would be a predictable disappointment in erysipelas, furunculosis, pneumonia, pyelitis, cellutis and bacteremia, and in cystitis except by concentrated irrigation. The use of this therapy would thus be limited to such closed organs as the intestine and to well encapsulated pus cavities. (Jour. A. M. A., February 28, 1931, p. 693.)

PROGRESS

Abstracts to be submitted to Section Supervisors.

Members are urged to abstract valuable articles which they run across in their reading and send the abstracts to the physicians in charge of the respective sections. In order to avoid duplication it would be well to communicate with one of the section supervisors before the article is abstracted.

EYE, EAR, NOSE AND THROAT

THE OPERATIVE TREATMENT OF GLAUCOMA: Professor Doctor Emil de Grosz, Budapest, 1930. (Note: This article came as a pamphlet and has not been published, to the reviewer's knowledge, in a periodical.)

VON GRAEFE TERMINOLOGY

I. Inflammatory (congestive glaucoma
    a. prodromal stage
    b. acute
    c. chronic
    d. absolute
    e. stage of degeneration
II. Simple glaucoma
III. Juvenile glaucoma

In simple glaucoma the leading signs are missing or inconspicuous. Correct diagnosis can only be made by objective findings such as excavation of the optic disc and shrinking of the visual fields. The degree of recovery depends essentially on the length of time the eye has already been affected.

In the Budapest clinic the frequence of the different types was as follows: chronic congestive eyes 70 per cent, cases in the prodromal or acute stage 20 per cent, simple glaucoma about 10 per cent, and the juvenile type less than 1 per cent.

In the types of operative procedure used iridectomy has kept its important role, while trephining was employed in numerous cases at the beginning and cyclodialysis more frequently at the end of the period. With the trephine procedure favorable results were obtained in 83 per cent of the chronic congestive cases but in the absolute cases the results were much poorer. The incidence of late infection can be markedly reduced if the fistula is carefully covered with a flap.

In the cases in which cyclodialysis was used the tension was decreased in 78 per cent of the chronic congestive type. The results proved to be better with simple glaucoma but less favorable with absolute. Cyclodialysis has the advantage of low operative risk and may be repeated two to four times. If it is a failure it may be followed by trephining.

In cases of simple glaucoma sclero-iridectomies were usually performed, with favorable results due to reduced tension in 94 per cent; the eyesight remained unchanged in 92 per cent, became better in 5 per cent and worse in 3 per cent. The favorable results decreased to 76 per cent in the years following. These percentages were obtained only in those cases in which the tension was successfully reduced by pilocarpine.

Anterior sclerotomy was performed in the juvenile type and in those cases in which cataract extraction had been done through an iridectomy.

In conclusion, surgical intervention, supported by frequent use of pilocarpine, is so far the most effective means of relief for glaucoma. With regard to the adequacy of operations performed on different kinds of glaucoma, the following principles are observed at the Budapest University Eye Clinic:

Inflammatory glaucoma, prodromal and acute—iridectomy (Graefe)
Inflammatory glaucoma, chronic—cyclodialysis (Heine)
Glaucoma, simple—iridosclerotomy (Lagrange)
Glaucoma, juvenile—anterior sclerotomy (Wecker)
Glaucoma, stage of degeneration—enucleation (Arlt)

L. G. Flanagan.

MEDICINE

TUBERCULOSIS ABSTRACTS*

Adolescence is a period of strain. Youngsters who have, during the earlier years of childhood, been massively infected with tubercle bacilli are likely during the teen age period to develop the adult type of tuberculosis. It is during high school years that the destiny of many of these children is decided. This is reflected in the steep rise in the death rate curve during the late teens and early twenties. Walter L. Rathbun has, since 1923, made a systematic search for early tuberculosis, regardless of symptoms, by means of the tuberculin test and the X-ray. He has recently completed the task of examining practically every high school pupil in Chautauqua County, New York; namely, 7,171 children. His experiences are recorded in a special publication, from which these abstracts are derived.

Tuberculosis Among High School Students

Examinations of school children for early tuberculosis began in Chautauqua County, New York, in 1923 by sending to local clinic centers (a) pupils physically below par, (b) those who had symptoms referable to tuberculosis and (c) those who have been exposed to the disease. The results of the first year's effort were enlightening, but since facilities were limited, it was decided the next year to examine only the high school groups because these children leave school first. Each high school student was given a chest examinaiton without reference to family history, height-weight ratio, or symptoms. The results justified the procedure as many cases of tuberculosis were found among those in whom it was least suspected and who were apparently perfectly healthy.

Of the students so examined, three groups were then X-rayed; (a) those with suggestive signs of pulmonary tuberculosis; (b) those in actual contact with a case of tuberculosis; (c) those with a history of previous or present symptoms referable to tuberculosis. All such children were transported to Newton Memorial Hospital, where they were X-rayed. This procedure continued during 1924 and 1925, when the plan was broadened by carrying the diagnostic work directly into the schools.

EXAMINATIONS MADE IN SCHOOLS

The Chautauqua County Tuberculosis Association furnished funds to purchase a portable apparatus and X-ray films which made it possible to do the work in the school buildings. Incidentally, while it is true that the portable X-ray machine has its shortcomings, it is capable when properly handled of revealing lesions of the childhood and the adult type. The few cases in which more detail is needed may be X-rayed with a high-powered machine. The utility of the portable apparatus is a distinct advantage, and having the examinations made in the school arouses interest among school people. Stereoscopic sets of pictures were made routinely.

In 1926, the mode of procedure was again modified. Students were taken from the study halls and X-rayed, and only those with definite or suspicious signs were given a physical examination. This speeded up the work and also increased the percentage of positive cases. The tuberculin test was not insisted upon as a routine measure at that time because public opinion was not favorable to its use, whereas X-ray examinations were heartily approved.

In 1927, the intracutaneous tuberculin test was introduced as the first procedure in diagnosis. A specially trained nurse made the test and read the reaction, thus saving valuable time of the physiican. It was neces-

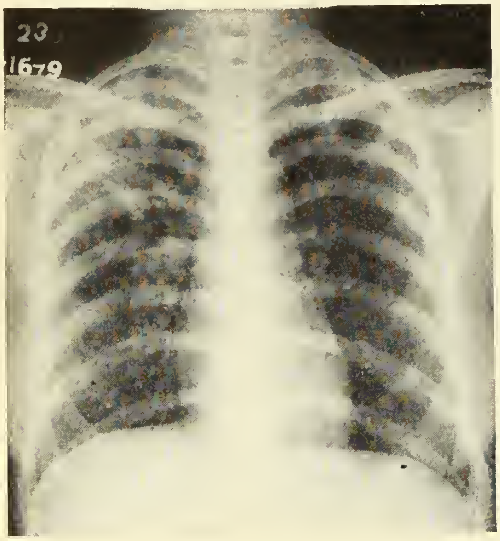
---

*Reprinted from *Tuberculosis Abstracts*, a review for physicians, issued monthly by the National Tuberculosis Association, April, 1931, Vol. IV, No. 4.

sary to secure the consent of parents to make the test; hence, the percentage tested was reduced to about 50 per cent. Positive reactors only were X-rayed.

INTIMATE CONTACT IMPORTANT FACTOR

These studies indicated that tuberculous disease of the lungs and tracheobronchial lymph nodes results from prolonged and intimate, rather than casual, exposure to tubercle bacilli. Intimate exposure most commonly takes place in the home. It was found that the percentage of positive reactors was greater among children living in the city of Jamestown (44%) than among similar groups in the villages (25%) but that the incidence of tuberculous disease of the childhood type was about the same in rural and urban areas. Apparently, while casual contact (which is more common in cities) may be the starting point of an infection as revealed by the tuberculin test, it is incapable of causing demonstrable disease in most cases. Intimate contact with a sputum-positive case of pulmonary tuberculosis is the usual cause of the disease. In 54 per cent of the families of tuberculous children, a parent had either died of the disease or had pulmonary tuberculosis at the time. In 17 per cent of the families, there was a parent with suspicious signs of tuberculosis. In some cases, the "spreaders" were older siblings, in one, a nurse-maid, and in another, a boarder.



Mottling in right upper and upper part of lower lobe, cavities in right upper, scattered mottling throughout upper two-thirds of left upper lobe with cavity near apex. Calcified lymph node above sternal end of left third rib, indicating presence of childhood type lesion.

Girl, 15 years old, very active in scholastic, social, and athletic affairs. Denied symptoms until questioned closely. Diagnosis made during routine school X-ray examination.

RESULTS OF STUDY

During the past seven years, 30,000 pupils, 7,171 of whom were of high school age, have been examined, with the following results:

	Number	Per cent
Negative to tuberculin test	570	7.9
Negative on X-ray	5,676	79.2
Children requiring observation	538	7.5
Childhood type tuberculosis	250	3.5
Suspect adult type tuberculosis	50	.7
Adult type tuberculosis	60	.84
Miscellaneous	27	.36
	7,171	100.

Cases of childhood tuberculosis were 15 per cent higher for females than for males, while the morbidity for the adult type was 43 per cent higher among females than among males.

Many of the arrested cases continued school work but were given eight weeks' treatment in a high school health camp located on the grounds of the hospital. During the past two years, a high school has been conducted for students under treatment in the hospital. Local school authorities are well satisfied with the experiment. For ambulatory cases and some bed cases, school work is the most profitable kind of occupational therapy.

PROTECTING THE STUDENTS' HEALTH

The tendency in modern schools is to push the students to the limit of their capacities. Healthy children can stand the pace, but not those who are below par physically. Therefore, those with physical disabilities, real or potential, must be searched for and protected from overwork. Similarly, sports and competitive athletics must be curtailed for the physically handicapped. Rough handling and excitement are heavy drains on the body reserve and frequently precipitate a breakdown. School authorities in Chautauqua County coöperated admirably in protecting those who needed protection.

The public schools are logical centers for the dissemination of medical knowledge about tuberculosis, just as they serve as convenient units for discovering cases. Every student should be examined before graduating and certainly before working papers are granted.

Of course, no child with positive sputum should be allowed to attend school lest he infect his fellows.

"Every available resource than can be spared should be devoted to the public school field, for in the control of tuberculosis our hope of success in the years to come rests largely upon the care of the youths of today."—*Health in High Schools, Walter L. Rathbun, Natl. Tuberc. Assn.*

ALTERNATING PNEUMOTHORAX: I. D. Bronfin, M.D., Denver, Colo. (Nat'l Tuberc. Assn.—Trans. Twenty-Sixth Annual Meeting, Memphis, Tenn., 1931). The principles governing pneumothorax therapy have undergone striking modification during the past ten years. The indications for this form of treatment were at first confined to strictly unilateral cases. Experience has shown that proliferative and even fibrocaseous processes in the good lung, when not too extensive, improve after a satisfactory collapse of the more involved lung. The further observation that a moderate reduction in lung mobility, instead of complete collapse, does not lead to bad results as was at first believed, but on the contrary brings about definite improvement, led some physicians to the rather heroic measure of simultaneous bilateral compression.

A review of the literature on simultaneous bilateral pneumothorax discloses that the encouraging results reported are not entirely conclusive, because of the short period of observation. The work of Kinsella and Mattill convinces one that bilateral pneumothorax is feasible in a certain number of cases and for definite emergencies, but leaves one in doubt as to the efficiency of this treatment. Kerzman reports 19 cases, of which several showed marked clinical improvement, but issues a warning that the procedure is justified only when all other methods have failed. On the other hand, the need for resorting to alternating or successive pneumothorax will continue to increase, because with the increase of the use of pneumothorax in the treatment of cases with bilateral lesions, reactivation of the old lesion or progression of the disease in the untreated lung will not be an uncommon complication. Also a large number of patients with apparently unilateral disease develop contralateral lesions during penumothorax therapy.

Six cases are reported in which alternating pneumothorax was used and the clinical course was observed for from two and one-half to seven years.

Case I. (Example) The indication was an acute contralateral involvement twenty-one months after the first pneumothorax was instituted. The second pneumothorax was maintained for twenty-six months. The lesions on both sides were of the exudative variety and the result was an apparent arrest of the disease.

Conclusion: Many patients who develop contralateral disease during pneumothorax therapy or have bilateral disease equally distributed, can be treated successfully by means of alternating pneumothorax, and in some instances will accomplish a complete arrest of the disease.

PEDIATRICS

THE THERAPEUTIC USE OF MIXED RESPIRATORY VACCINES: Roy P. Forbes, M.D., Denver, Colo. (Arch. of Ped., January, 1931, Vol. XLVIII, No. 1). The status of vaccine therapy seems to be as dubious and hazy now as it was one or two decades ago.

Davis concurs in the belief that prophylactic immunization against colds is not of value in early childhood. He asserts, however, that the procedure apparently is of value for older children and adults.

It was quickly noted that cases in which cough accompanied the upper respiratory infection were frequently relieved after one to three injections. Where there was clinical evidence of sinusitis, the nasal discharge sometimes at first increased, then subsided.

Vaccine therapy was reserved for those cases which suffered a relapse and had cough as a prominent symptom. It often gave prompt relief to these children. Usually one injection was sufficient to loosen and relieve the dry cough, and in many instances children with severe bronchitis and early broncho-pneumonia made a prompt recovery in 48 hours. However, the other complications, such as adenitis, otitis, and mastoiditis, were apparently unaffected by the vaccine. They found that a total of 211 house calls were necessary for the vaccine-treated cases, as compared with 300 house calls on the control series in 100 cases each. It is of interest to note that no case in the vaccine series developed either bronchitis or pneumonia after treatment was begun, whereas in the control series five children developed pulmonary complications while under careful medical supervision.

The therapeutic value of the vaccine in respiratory infections has not been widely demonstrated, and there are, as yet, comparatively few reports of such usage, but the reports which have been made are generally favorable. The writer's experience leads him to conclusions highly favorable to the use of respiratory vaccine as a therapeutic agent in certain infections of the respiratory tract.

R. N. Andrews, M.D.

ACUTE INTUSSUSCEPTION IN INFANCY: OPERATIVE AND NON-OPERATIVE TREATMENT: David M. Siperstein, M.D., Minneapolis (Arch. of Ped., January, 1931, Vol. XLVIII, No. 1). Intussusception is typically a disease of infancy. It is an acute condition requiring prompt recognition and prompt treatment. It occurs chiefly during the first year of life, especially between the fourth and tenth month.

Koch and Oerum feel that this condition is caused by a preliminary circular contraction of the gut followed by an overlapping. Fraser considers that abnormal and irregular peristaltic rhythms are responsible. He find that, "if the ileocecal segment is provided with a loose mesenteric attachment, the occurrence of a peristaltic rush is likely to be followed by the development of intussusception."

Perrin and Lindsay offer the most logical explanation thus far advanced and accompany it by histological proof. They point out the obvious development of lymphoid tissue at the ileocecal valve and its rapid subsidence during the second year of life. The incidence of intussusception is directly proportionate to the development of the lymphoid tissue in this particular area. This theory explains the characteristic age incidence, and it explains the frequency of the ileocecal type.

Acute intussusception is characterized by four cardinal symptoms: The first of these is abdominal pain; the second, vomiting; the third, blood and mucus in the stool; the fourth, a palpable tumor mass.

A comparison of the mortality statistics with various forms of treatment tends to show that, with proper selection and precautions, mechanical interference gives excellent results.

In the hands of a surgeon skilled in pediatric procedure, disinvagination of an acute intussusception is a relatively simple and safe procedure. In any questionable case, this might be the method of choice. Early diagnosis and prompt treatment should definitely lower the mortality of acute intussusception. The surgical and non-surgical procedures are not competitive methods. They should complement one another under the careful supervision of the trained pediatrician and surgeon.

R. N. Andrews, M.D.

ACUTE PHOSPHORUS POISONING: Eleanor M. Humphreys, B.A., and Bela Halpert, M.D., Chicago (Amer. Jour. of Diseases of Children, Vol. 41, No. 2, February, 1931). The incidence of phosphorus poisoning has decreased greatly in recent years. Undoubtedly the decrease is due mainly to the prohibition of the manufacture and sale of yellow phosphorus matches. In this country there are still two easily available sources of yellow phosphorus: certain brands of rat and roach paste and certain types of fireworks.

In communications to the editor of the Journal of the American Medical Association, Stacy, Busey, and McCornack discussed the case of the fifteen months old son of Dr. Stacy, who ate the unburned remnant of a Devil-on-the-Walk and died four days later. Corwin recorded the death of a three year old girl, forty-six hours after placing a Spit-Devil in her mouth.

The risk of acute phosphorus poisoning has been decreased but not eliminated by the prohibition of the manufacture and sale of yellow phosphorus matches.

The ingestion of fireworks containing phosphorus is a cause of acute phosphorus poisoning in children.

A review of the medical literature reveals a total of twelve reported cases. There is evidence that this figure does not give a true idea of the frequency of phosphorus poisoning caused by fireworks.

The commonly implicated agent is a single type of fireworks, variously known as "Son-of-a-Gun," "Devil-on-the-Walk," and "Spit-Devil."

SURGERY

THE MIXED TUMORS OF THE SALIVARY GLANDS. D. H. Patey (The Brit. Jour. of Surg., October, 1930, p. 241). A study of fifty-five cases of mixed tumors of the salivary glands treated at the Middlesex Hospital since 1919.

Based upon the histological appearance of the tumors, a division is made into four types: (1) "typical" tumors, (2) cellular and not well differentiated, (3) cellular but well differentiated, (4) cellular and not well differentiated and cells showing irregularity and nuclear changes. In the first group are cases with relatively few cells, which are small, irregular and deeply staining and with an abundance of myxomatous tissue. In the second group are those in which there is a relative abundance of the cellular element. In the third group the cells are arranged in acini or ducts much like nests of fairly normal glandular tissue. In the fourth group are cases showing malignant tendencies.

The derivation of the tumors is believed to be from epithelial tissue entirely, instead of being mixed epithelial and mesenchymal tissue. The myxomatous portion is believed to be a derivation or product of epithelial cells.

In this series of fifty-five cases, thirty-eight were in the parotid gland, six in the submaxillary gland and five in the palate. Six were in other regions about the face.

Recurrence after operation was present in eleven out of the thirty-eight parotid cases and in other regions the percentage was about the same. One recurrence occurred as late as nineteen years after operation.

The recurrent tumor was encapsulated or infiltrating. There was no evidence of a greater tendency to malignancy in the recurrent cases. The group showing malignant tendencies, *i.e.,* group four, definitely had a higher percentage of recurrences. In the other three groups the recurrences occurred in about equal percentages.

The causes of the recurrences were two: incomplete removal and development of new and independent tumors. The tumors not infrequently showed small daughter tumors on the edge, which could easily be left behind.

The treatment suggested was surgical removal although the more cellular varieties might give good results by treatment with radium.

R. W. Koucky, M.D.

PUSH FLUIDS: G. De Takats, M.D., F.A.C.S., Chicago, Ill. (Amer. Jour. of Surg., No. 1, Vol. XI, January, 1931). Under the above heading, the author treats the subject of the giving of fluids after operation; because of the fear of dehydration, it has become a routine to order fluids to be pushed after operation. While in general this is correct, yet one must individualize the case, and take into consideration the mechanics of water retention and water excretion, and regulate the use of fluids accordingly. It is possible to overload the system, and develop a water intoxication, which in itself is detrimental.

The author reviews the movement of water through the system (1) from the standpoint of cardiac action, (2) from the condition of the kidneys, (3) from the condition of salt retention, and (4) from the pathologic changes in tissues.

Realizing that after an abdominal operation the intestines frequently contain fluid, one does not get sufficient absorption of fluids by rectal drip in many of these cases, and may only aggravate the discomfort of the patient. Therefore, the giving of fluids through the skin, or intravenously, is preferable. Then also the absorption of dextrose per rectum is often very little, which, while harmless in itself, yet may give a false sense of security by the fact that one really is not supplying dextrose to the system; on the other hand, insulin used under such circumstances may cause an insulin toxemia.

To sum up the article, the author calls attention to the water balance as it exists in the individual patient, rather than in the normal person, keeping these facts in mind in applying one's use of fluids. In general one can say that, where an oral intake of fluids after operation is prevented, a satisfactory water balance can be maintained with 3,000, and not more than 4,000, c.c. of fluids. Much of this fluid can be given under the skin in the form of 5 per cent dextrose solution, but in some cases the intravenous drip of 10 per cent dextrose solution is indicated. If the salt balance is disturbed, Ringer's solution under the skin is preferable.

The order to push fluids should not be given unless one checks up the results of this pushing, and maintains the proper physiological balance.

A. E. Sohmer, M.D.

SPONDYLOLISTHESIS: Samuel Kleinberg, M.D., (Amer. Jour. Surg. Vol. X, Dec., 1930, p. 521). The author reports four cases of spondylolisthesis in which the dislocation of the fifth lumbar vertebra was due to congenital deformity of its posterior arch. The most important congenital anomaly in relation to spondylolisthesis is a congenital cleft in the pedicles due to lack of fusion of the superior and inferior articular processes of the fifth lumbar vertebra on one or both sides. This defect is filled in by connective tissue, and the vertebral body and neural arch are held together only by ligaments which may be stretched or torn by trauma. This was the mechanism of the dislocation in two of the author's cases.

An increase in the lumbosacral angle is another factor in the production of spondylolisthesis. Combined with this there may be a change in the shape of the superior margin of the sacrum in which the upper surface is convex and the anterior half slopes downward and forward. This condition tends to initiate subluxation of the last lumbar vertebra during ordinary occupation. Another factor is an alteration in the plane of the lumbosacral joints which may be oblique or horizontal and thus predispose to subluxation. Elongation of the laminæ was the cause of slipping in two of the author's cases.

Most authors are agreed that trauma is a prominent factor in the etiology of the majority of the cases. A single severe trauma or a succession of injuries may produce the condition in those that are predisposed by congenital malformations.

Several plates illustrate the condition and show the value of X-ray examination.

Jacob Sagel, M.D.

BRINKLEY'S BROADCASTING STATION

The Federal Radio Commission refused to renew the broadcasting license of Station KFKB, of Milford, Kansas, operated by John R. Brinkley, because it was operated mainly in the interest of Brinkley and his associates rather than in the interest of the public. Brinkley appealed the case to the courts but this appeal has been denied. (Jour. A. M. A., February 14, 1931, p. 547.)

BOOK REVIEWS

Books listed here become the property of the Ramsey and Hennepin County Medical libraries when reviewed. Members, however, are urged to write reviews of any or every recent book which may be of interest to physicians.

BOOKS RECEIVED FOR REVIEW

Modern Methods of Treatment. (Fourth Edition). Logan Clendening, M.D. 819 pages. Illus. Price, $10.00. Saint Louis: The C. V. Mosby Company, 1931.

Abdomino-pelvic Diagnosis in Women. Arthur John Walscheid, M.D. 1000 pages. Illus. Price, $12.50. Saint Louis: The C. V. Mosby Company, 1931.

How It Happened. A. G. Bettman, M.D., F.A.C.S. 110 pages. Price, $1.00. Philadelphia: F. A. Davis Company, 1931.

Common Contagious Diseases. Stimson. 353 pages. Illus. Price, $3.75. Philadelphia: Lea & Febiger, 1931.

General Medicine, Practical Medicine Series. Weaver, Brown, Minot, Stroud, Brown. 848 pages. Price, $3.00. Chicago: The Year Book Publishers, 1930.

Cancer. Willy Meyer. 427 pages. Illus. Price, $7.00. New York: Paul B. Hoeber, 1931.

Textbook of Human Embryology. Cleveland Sylvester Simkins, Ph.D. 469 pages. Illus. Price, $4.50. Philadelphia: F. A. Davis Company.

DISEASES OF THE GENITO-URINARY SYSTEM IN INFANCY AND CHILDHOOD (Clinical Pediatrics, Volume XIX). Henry F. Helmholz, M.D., and Samuel Amberg, M.D. Supervising Editor, Royal Storrs Haynes, Ph.B., M.D. 239 pages with contents, 27 illustrations, 43 cases, references at the end of each of the eleven chapters, and an index. Price: $85.00 per set of 20 volumes and general index. Sold only in sets. New York, London: D. Appleton & Co., 1930.

This volume reads like all of the highly dependable, well organized, very helpful works of the authors. It combines the experimental with the clinical; is clearly lucid, concise and to the point. The references are very complete and cover even the most recent contributions. The illustrations and cases are very clarifying. It is to be highly endorsed and recommended in its entirety for the student, pediatrician and general practitioner. There is a human key-note throughout—let pediatricians be keenly alert to safeguard the child by a correct diagnosis for the future health of the adult.

Lillian L. Nye, M.D.

GENERAL MEDICINE: The Practical Medicine Series. Edited by George H. Weaver, Lawrason Brown, George R. Minot, William B. Castle, William D. Stroud, and Ralph C. Brown. Cloth. Price $3. Pp. 830. Chicago: The Year Book Publishers, Series 1930.

The general arrangement of the volumes, eight in number, in this series, is familiar to the profession. The book is divided into five parts. The first, on Infectious Diseases, emphasizes the newer diseases, as psittacosis, undulant fever, and tularemia; aspects of newer methods in treatment, as the use of whole blood in measles, immune serum in poliomyelitis, and the prevalence of epidemic diseases in various parts of the country. Part 2 takes up diseases of the chest (excepting the heart). Home and sanatorium treatment of tuberculosis is discussed, as are special measures, vaccine, diet, rest, lung collapse, and diagnosis. The bulk of the section is on tuberculosis. Part 3 reviews the years' literature on the blood and blood-making organs. There is considerable discussion of the reticulocyte count in health and disease; of nomenclature in the anemias, of anemia as a deficiency disease, of the extent and nature of the response, in anemia, to liver and liver extract, of transfusion, and some of the rarer blood diseases. A most interesting section. Part 4 deals with diseases of the heart and blood vessels. The discussion follows the general headings of etiology, anatomical considerations, physiological abnormalities, treatment, and miscellaneous topics. The final section is devoted to diseases of the gastro-intestinal tract, and diseases of metabolism.

E. C. Hartley, M.D.

ARTERIAL HYPERTENSION. E. J. Stieglitz, M.D., Assistant Professor of Clinical Medicine, Rush Medical College, Chicago. Price $5.50. New York: Paul B. Hoeber, 1930.

The presentation of a subject the etiology of which is practically unknown is here well done. The author has exhaustively gathered together facts pertaining to this condition, and has done much to present the subject in a clarified manner which will be appreciated by the general practitioner. It is essentially a careful review of the literature with a resulting presentation of our present knowledge of the subject, and indications of lines of research which should be undertaken.

The underlying anatomy, and physiology, and the pathogenesis of hypertension is given satisfactorily. The difficulty of treatment is well recognized, and the views of various workers are given with remarks concerning the author's opinion of them. The question of hypertension in pregnancy is adequately considered, and the problem of the management of the late results of the condition, cardiac and renal, is discussed without noteworthy alterations from accepted opinions.

Summarizing, the author has presented a live subject in a most satisfactory manner, and the monograph, well written, should be of real interest to the practitioner.

Joseph A. Borg, M.D.

WANTED—Salaried appointments for Class A Physicians in all branches of the medical profession. Let us put you in touch with the best man for your opening. Our nation-wide connections enable us to give superior service. Aznoe's National Physicians' Exchange, 30 North Michigan Ave., Chicago. Established 1896. Member The Chicago Association of Commerce.

WANTED—Part time appointment by Minneapolis physician. Address D-125, care of Minnesota Medicine.

PHYSICIAN'S OFFICE FOR RENT—Best location Midway district, corner Thomas and Hamline, Saint Paul. Rent $25.00 a month. Inquire at dentist's office.

WANTED—Recent (German speaking) graduate to take over my practice. Must be of good habits and well qualified. Nothing to sell. Address D-124, care of Minnesota Medicine.

FOR SALE—Minnesota—In town of 2500, rich German community, on Jefferson and Coast to Coast Highways, well established practice, five bed hospital, residence combined, well equipped office. Will consider partner with small investment, or sell at sacrifice a $15,000 yearly cash practise. Reason: Poor health. Address D-128, care Minnesota Medicine.

WANTED—Position by experienced medical secretary. Graduate Medical Secretarial Course, Rochester, Minnesota. Address D-127, Minnesota Medicine.

POSITION WANTED—By Laboratory Technician skilled in Physiotherapy, X-Ray, Basal Metabolism. College Graduate. Hospital training and experience. Address D-126, c/o MINNESOTA MEDICINE.

FOR SALE—Lease of office, 516 La Salle Building, Minneapolis, and complete office and X-ray equipment of the late Dr. H. N. Meleck, including goodwill and referred work from six industrial and insurance firms. Office may be inspected any time during the day. Telephone Geneva 5592.

FOR SALE—All furniture and equipment for modern seven room hospital. In splendid condition. Bargain if interested. Address D-129, care Minnesota Medicine.

INSTRUMENTS FOR SALE

An exceptionally complete set of surgical instruments and office equipment, property of the late Dr. Lyng, is for sale. Especially suitable for hospital. May be seen at 5145 Woodlawn Avenue, Minneapolis. Telephone Dupont 8948.

VOL. XIV MAY, 1931 No. 5

RESULTS IN PERINEAL PROSTATECTOMY*

AN ANALYSIS OF THREE HUNDRED AND TWENTY-THREE CONSECUTIVE CASES

Edwin Davis, M.D.
Omaha

PROSTATECTOMY, like all other surgical procedures, has a two-fold purpose, the prolonging of life and the relief of suffering. In analyzing the results of prostatectomy, with the purpose of determining what is to be expected from this operation, we are therefore primarily interested in: (1) the immediate mortality rate, and (2) the late functional results. For obvious reasons, the second of these considerations is almost as important as the first.

In answering the question as to what prostatectomy has to offer to the patient, we must be guided by statistical data, covering the mortality rate and the percentages of immediate and late complications, as well as the percentage of satisfied or well patients. Data for such a purpose may be best obtained by an analysis of a series of similar cases, handled in the same manner and preferably by the same diagnostician and the same surgeon. The larger the series, the less the inaccuracy in the conclusions. It is my purpose briefly to present two tables summarizing the immediate and the late results in a consecutive series of 323 cases of perineal prostatectomy under sacral block anesthesia. Since this paper is intended merely as a brief presentation of operative results, all details of diagnosis, preparation and operative technic have been purposely omitted. In a recent publication[1] I summarized the immediate and late results in a series including 176 cases of perineal prostatectomy under sacral block anesthesia. The tables here presented include the above data, plus the additional information gained from 147 subsequent cases, similarly handled.

IMMEDIATE OPERATIVE RESULTS

Prostatectomy is no longer the hazardous procedure of former years, with a mortality rate of 20, 30, or 40 per cent, although this idea still persists to a very considerable degree in the mind of the laity and of many members of the profession as well. Authentic figures, available from several urological clinics, go to prove that the risk of this operation, during comparatively recent years, has been reduced to almost nil, so that the statistics of prostatectomy upon the aged may now compare very favorably with, for instance, the statistics of herniotomy upon the young and robust. There are three essential factors which have contributed largely toward this conspicuous lowering of the mortality rate of prostatectomy. These are: (1) proper preoperative preparation; (2) sacral block anesthesia; and (3) complete hemostasis.

Preliminary Drainage.—The first, and the most important of these, preliminary drainage, is a subject which has been dwelt upon in recent years in many publications by competent authorities, and the importance of which has become too well recognized to require discussion at this time. The neglect of this most essential phase of the subject of prostatectomy will have, as its inevitable consequence, an appalling mortality rate. Each patient in this series, upon entering the hospital, was advised that the period of preliminary bladder drainage averages three weeks. Many of them spent a considerably longer period in the hospital prior to the operation, while a few were sent home with suprapubic drainage tubes for periods ranging from one to several months. In no other way than by attending to this important item with scrupulous care and rigid insistence, is it possible to avoid unnecessary prostatectomy deaths. Even in the case of patients in apparently splendid condition, and with satisfactory renal functional tests, I have adopted a ten-day preliminary drainage period (with normal temperature) as a minimum, and deviate from this rule under no circumstances. Patients insisting upon immediate operation, and fretting because of the delay, are advised that they are at liberty to go elsewhere.

---

*From the Department of Urology, University of Nebraska College of Medicine. Presented before the Southern Minnesota Medical Association, Mankato, Minnesota, August 25, 1930.

Sacral Block Anesthesia.—It may be stated without exaggeration that the sacral block method affords an ideal form of anesthesia for perineal prostatectomy. In a word, sacral block anesthesia is easily and quickly administered, it carries with it no hazard, and is entirely dependable. In fact (as figures cited below will show). the sacral block method may truthfully be said to be infallible in producing results, if properly administered. This method is also admirably suited for suprapubic prostatectomy, although, for this route of approach, additional local infiltration anesthesia of the abdominal wall must be provided. It is quite important to point out with emphasis that sacral anesthesia differs essentially from spinal anesthesia in being extradural, while the latter is intradural and carries with it a certain hazard of its own. Other than this statement, the details of technic of sacral anesthesia have been purposely omitted, since this subject has been fully covered elsewhere.[2]

Assuming familiarity with the technic, the complete sacral block injection may be carried out with comparative ease in about ten minutes' time. The risk is negligible, in that there has not been an anesthesia death during the entire series; neither has there been a reaction of consequence. Although slight reactions, characterized by a moderate drop in blood pressure and by more or less pallor and perspiration and more rarely by nausea, are not uncommon, there has not been a single instance in which the reaction was in any measure alarming.

The chief objection to the sacral method in the hands of different observers has been the rather small percentage of cases in which there has been inexplicable failure to produce satisfactory anesthesia. The figures here presented, and those presented in a former paper published in 1924, are of interest in this connection, and tend to throw some light upon the cause of this occasional failure. In this former paper[3] I reported a series of thirty consecutive cases of perineal prostatectomy under sacral block anesthesia. Among this series, three were complete failures, while four required additional gas inhalation anesthesia during the final stages of enucleation. Thus, seven out of thirty, or 23.3 per cent, were unsatisfactory for reasons not understood. In the present series, there has not been a single case requiring gas inhalation anesthesia during the last 172 consecutive cases; and out of the last 230 cases, gas has been necessary during the final stages of enucleation in one instance only. Thus the percentage of failure has been reduced from 23 per cent to 0.4 per cent. Since in all instances the same drug in the same concentration has been employed, and since there has been no deliberate modification in the technic of injection, the only logical conclusion is that through practice the anesthetist has learned to place the needles more accurately. In other words, it is possible for the anesthetist to be mistaken in considering that the needle point has been properly placed within the caudal canal or in the foramina, and the percentage of failures may thus be adequately explained upon a technic basis, without recourse to the various anatomical and physiological theories which have been advanced. It may, therefore, be conservatively stated that sacral block anesthesia for perineal prostatectomy is free from risk and is uniformly efficient when properly administered. Thus the method of anesthesia which is easy, safe, and infallible leaves nothing to be desired.

Hemostasis.—In addition to the group of prostatectomy deaths due directly to hemorrhage, there is another larger group in which death later results indirectly from hemorrhage, by reason of infection secondary to lowered resistance. The importance of hemorrhage as a mortality factor is probably underestimated by reason of failure to recognize the primary cause of death in this second group of cases. The necessity for detailed attention to complete hemostasis, therefore, cannot be overemphasized, and, for the same reason, haphazard hemostatis in prostatectomy will have its inevitable consequence in a certain percentage of cases. It is quite true that the majority of patients, properly prepared, will survive by the trust-to-luck method of hemostasis, but if the minimum mortality rate is to be achieved, this important item is not to be neglected.

Prostatectomy may ordinarily be accomplished with very little bleeding, and in many instances the operation may be made almost bloodless, as the result of: (1) the opportunity for deliberateness in controlling individual bleeding points in and around the prostatic capsule by suture and ligature, through the time afforded by the use of sacral anesthesia; and (2) the use of an inflated hemostatic bag for the purpose of controlling hemorrhage during the first few post-operative hours. For this latter purpose, in all the cases here reported, a perineal prostatic hemostatic bag, described in a previous publication,[4] was employed. This bag (Fig. 1) is a distensible cone-shaped balloon, which is introduced through the internal sphincter into the bladder immediately after the enucleation of the gland; and the apex of which is maintained in the prostatic urethra in such a manner as to fill the prostatic cavity snugly, and (which is more important) to retain, rather than evert, the torn edges of bladder mucosa. This bag differs from the Hagner suprapubic bag in two essential respects:

1. The perineal bag is maintained in place by means of direct traction via the perineal incision (and counter-traction against the perineum), rather than by indirect traction via the urethra.
2. In the absence of a suprapubic fistula, adequate provision for urinary drainage is accomplished by means of a large, through-and-through, stiff-walled rubber tube, traversing the bag from apex to base, without communicating with the interior.

The caliber of this through-and-through drainage tube (internal diameter) is 0.25 inch. Communicating with the interior of the bag near its apex is a much smaller tube, through which the bag is distended. The traction loop of rubber, for maintaining the position of the bag, and later for facilitating removal, is attached to the large tube just at its junction with the apex. A tape passes through the traction loop, and through a hole in the center of an oval piece of metal, and traction is maintained by means of a screw-clamp, the oval metal having been placed flush with the skin surface immediately after closure of the incision. In place of the oval metal and screw-clamp, an ordinary hemostatic clamp (separated from the wound by a pad of gauze) may be substituted. The length of the bag (apex to base) is 6.5 cm., and its diameter at the base (when distended with 60 c.c. of water) is 4.5 cm.

The bag is introduced into the bladder through the prostatic cavity and the internal sphincter, immediately upon completion of the enucleation. After distension with air, traction upon the tape is immediately begun, which results in pulling the tissues surrounding the bladder neck down into the prostatic cavity, obliterating lax open spaces and compressing the torn edges of bladder mucosa. With rare exceptions, hemostasis is immediate, complete, and permanent. The traction is relaxed after three hours, the air released from

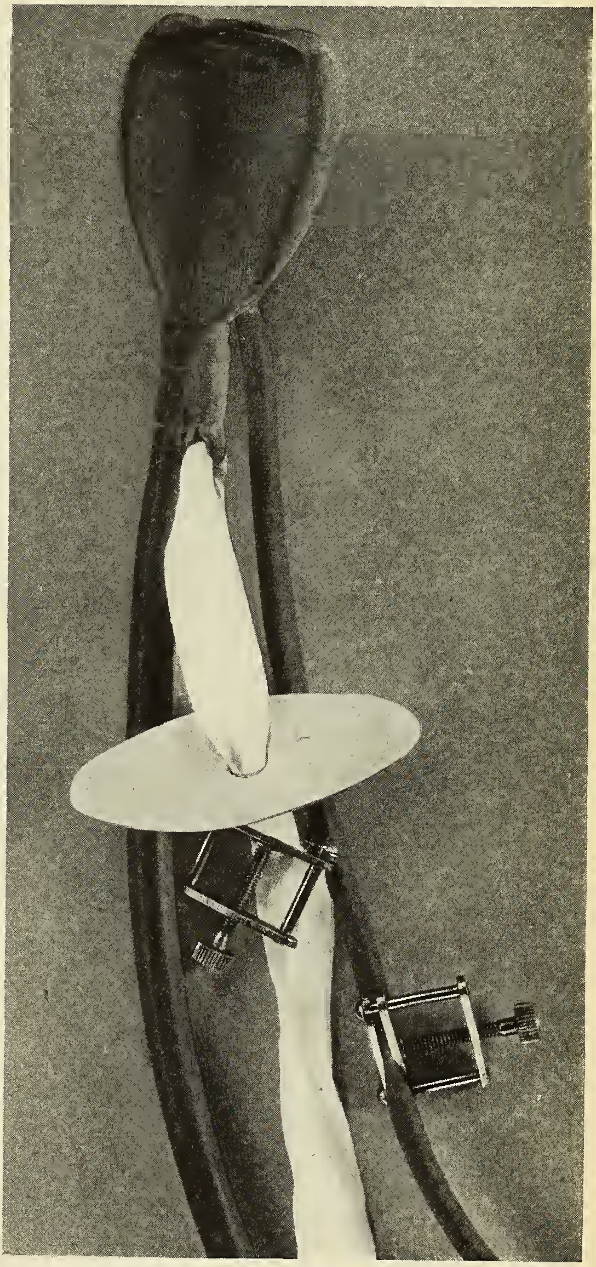

Fig. 1. Davis perineal prostatectomy bag.

the bag after twenty-four hours, and the collapsed bag is withdrawn through the perineal fistula after forty-eight hours. Immediately after the operation, the urine is usually yellow in color, and is seldom more than pink-tinted. Upon the rare occasions that hemorrhage recurs, the bag may be re-distended with air, the traction renewed, and the clots aspirated through the large, stiff-walled tube. A very efficient method of hemorrhage control during the first forty-eight post-operative hours is thus provided. It may, therefore, be stated without exaggeration that, with proper attention to preparation, anesthesia, and hemostasis, the problem of the immediate mortality of prostatectomy may be considered to be satisfactorily solved, with one reservation only. I refer to delayed hemorrhage. As may be noted in Table I, this complication has occurred in eight cases out of 323. Sudden, profuse hemorrhage, occurring as late as the tenth post-operative day, and interrupting an otherwise smooth convalescence, is a menace which may be neither foreseen nor prevented, and which occurs probably as the result of infection and slough. This constitutes a grave emergency, in that its seriousness may not be recognized until the patient has gone into collapse. Hemorrhage of this character is a complication which should not be temporized with, and which calls for immediate re-introduction of a bag or pack. In four of the above cases, an immediate suprapubic incision was made under local anesthesia in order to permit evacuation of clots and the introduction of a Hagner bag. Hemorrhage of this character was indirectly responsible for one of the eight deaths, in that the patient's resistance was lowered by loss of blood to such an extent that gangrenous infection of the incision set in, resulting in general sepsis and death ten days later. In this connection, it is of particular interest to note that one patient had two of these massive, exsanguinating delayed hemorrhages, occurring on the tenth and the thirty-sixth post-operative days, respectively. The first was controlled by a re-introduction of the bag through the perineal fistula, and the second by open suprapubic incision under local anesthesia. This patient survived. The amazing interval of time (thirty-six days) between the prostatectomy and the second massive hemorrhage is worthy of note, and serves to remind us that the delayed hemorrhage menace is ever present, although sufficiently rare to be conspicuous only in the large series of cases.

Table I

PERINEAL PROSTATECTOMY UNDER SACRAL ANESTHESIA
Immediate Results

Total consecutive cases	323
Average age	70
Above eighty	21
Deaths	8
Mortality rate, per cent	2.48
Total consecutive cases with no deaths	121
Sacral anesthesia (consecutive cases without failure)	172
Rectal injury	1
Postoperative "shock"	0
Delayed hemorrhage (several days)	8
Epididymitis	37

SUMMARY

The immediate operative results are shown in Table I. Although there were 121 consecutive cases without a death, there were eight deaths in the entire series of 323, a mortality rate of 2.48 per cent. This mortality rate represents a faithful and accurate recording of all deaths, due directly or indirectly to the prostatectomy, or occurring from any cause whatever during the patient's stay in the hospital. Among the eight deaths there has been included one which occurred on the thirty-ninth post-operative day. This patient was a very weak and frail old man of seventy-nine, who did well for the first three post-operative weeks, but who finally passed out from no apparent cause, other than lack of vitality and resistance. As an evidence of this he developed an abscess in the calf of the leg a few days prior to death. Since the site of the operation was in good condition, and since a period of thirty-nine days had elapsed, this was clearly not a prostatectomy death, yet this case has been nevertheless included. Of the seven other deaths, two were due to late general sepsis, three to renal insufficiency, one to pulmonary embolus, and the other to acute cardiac decompensation, occurring on the sixth post-operative day. One additional death, occurring on the fifty-first post-operative day (from renal insufficiency) I have considered could be honestly and properly excluded from the series, since this patient was up and fully dressed at the end of the third week and had been given permission to return home. Although the incision was entirely healed and although the urine was passing normally per urethra, this patient voluntarily chose to remain in the hospital awaiting the development of better urinary control.

The average age figure (70 years) is undoubtedly fairly accurate, although not representative of the entire series, in that this figure was compiled from 100 consecutive cases only. There were twenty-one patients above eighty years of age in the entire series.

With respect to the dependability of sacral block anesthesia, it is to be particularly noted that the necessity for additional gas inhalation anesthesia has arisen in not a single instance in the last 172 consecutive cases. As pointed out above, however, sacral anesthesia failures were much more frequent earlier in the series.

The one case of rectal injury at operation did not result in the development of an urethrorectal fistula because the urinary stream was diverted during convalescence by suprapubic aspiration, and because the location of the lesion was very low down upon the anterior rectal wall, just above the sphincter ani. This was due to an avoidable technical error at operation.

The subject of delayed hemorrhage, occurring about the tenth post-operative day (eight cases) has been discussed above.

There were thirty-seven cases of post-operative epididymitis, occurring during the first six weeks. This figure is too high, since epididymitis, occurring toward the end of a long period of hospitalization when the patient's morale has been all but exhausted, is a very trying and discouraging complication. For this reason I have since adopted preliminary bilateral vasectomy as a routine prophylactic measure, and shall subsequently publish comparative figures.

PERINEAL PROSTATECTOMY UNDER SACRAL ANESTHESIA

Late Functional Results

Total consecutive cases questioned	200
Time elapsed since operation	3 to 24 months
Patient's own opinion:	
Well	164
Improved	32
Unimproved	4
Incontinence:	
Complete	0
Inconvenient	2
Slight	3
Nocturia:	
Not at all or once	43
Once or twice	21
Two or three times	11
Four or more	11
Urinary fistula:	
Complete	0
Slight	6
Recto-urethral fistula:	
Immediate	0
Late	2
Retention of urine	1

LATE FUNCTIONAL RESULTS

Table II summarizes the late functional results as determined by questionnaire blanks returned from 200 consecutive patients. These data were compiled during May, 1928, and June, 1930. On account of the recognized impossibility of communicating with all of a consecutive hundred of these patients, 250 questionnaire blanks were sent out to as many consecutive patients. From the replies, those of the last consecutive 200 patients operated upon were selected. In order to avoid complications and misunderstandings, only the following simple, direct questions were asked.

1. Is the wound entirely healed?
2. Can you control the urine?
3. Do you pass urine too often?
4. How many times do you get up at night to urinate?
5. Does the urine pass without difficulty?
6. As far as the operation is concerned, do you consider yourself (1) well, (2) improved, or (3) unimproved.

The last question was considered to be the most important, since this was for the purpose of obtaining a voluntary expression of the patient's own opinion as to the result of the operation. As shown in Table II, 164 of these patients unequivocally state that they consider themselves well, while there are thirty-two improved and four unimproved. An analysis of these data shows that of those patients who list themselves in the improved group rather than in the well group, practically every one has done so on account of urinary frequency, or on account of some other wholly unrelated cause for which the prostatectomy cannot under any possibility be considered responsible. Such patients, however, have nevertheless been classified according to their whims rather than in accordanec with the known facts, since this table is intended to represent the patient's own unbiased opinion. In this connection it is to be noted that in a post-prostatectomy series, there would necessarily be a fair percentage of cases of advanced pyelonephritis and other chronic infections such as to prevent all possibility of the return of the urinary tract to normal. Therefore, even after the obstructive symptoms have been done away with by prostatectomy, the persistence of urinary frequency in a certain percentage of cases is inevitable. The average intelligent patient, however, recognizes that relief from obstructive symptoms is more essential than relief from minor degrees of urinary frequency. This is demonstrated by Table II. Although approximately only 60 per cent of these patients report themselves as being disturbed as few times each night as once or twice (or not at all), as many as 80 per cent voluntarily express themselves as being well.

The question of post-prostatectomy incontinence is a subject deserving careful consideration. Although there was no case of complete incontinence in this series of 200, there were two with a sufficient degree of incontinence to be a cause of considerable inconvenience. While each of these patients has intervals of complete dryness and has the ability to start and stop the urinary stream at will several times while voiding, there is a weakness of the external sphincter, as indicated by leakage, at intervals, of small amounts on any undue exertion, such as coughing or sneezing or suddenly rising. Since these patients have intervals of complete dryness, and since they have the ability voluntarily to start and stop the urinary stream, it is evident that a sphincteric structure exists and it is, therefore, logical to consider the possibility of individual anatomic variation in the musculature or innervation of the external sphincter. I have under observation at the present time, two patients with this identical type of sphincter weakness following suprapubic prostatectomy. In this connection, I do not intend to minimize the possibility of external sphincter injury by the perineal operation. It is to be frankly stated that this is a very real danger, particularly in those cases in which the internal sphincter has been rendered functionless by the gland itself. In addition to these two, there were three others with slight degrees of incontinence.

It is likely that in at least some of these five cases the unsatisfactory control resulted from technical error at operation.

One case of complete urinary fistula resulted from the formation of a fibrous stricture or septum at the apex of the prostate. Since this condition has subsequently been restored to normal by internal urethrotomy, this fistula no longer exists. The six patients with slight perineal urinary leakage each complained of the escape of a few drops of urine at intervals through the perineum at the time of voiding. In each case, this condition existed over a period of several months. Four of these have been subsequently cured by a secondary minor plastic operation. Another has been lost sight of. The sixth has a persistent perineal fistula in spite of a secondary attempt at plastic repair. Failure to obtain satisfactory healing in this case, however, may be explained by the fact that this patient shows a four-plus Wassermann test.

There has been no case of immediate postoperative urethro-rectal fistula. One patient, in a very debilitated and weakened condition, had a long, protracted convalescence associated with perineal pain and an elevated temperature over a period of three or four weeks. Five weeks after operation he developed a leakage of urine into the rectum, this fistula having occurred presumably as the result of a periprostatic abscess. Another developed an urethro-rectal fistula upon the tenth post-operative day, occurring presumably as the result of technical error at operation, although there was no evidence of rectal injury at the time. This fistula subsequently was successfully repaired by the Young-Stone operation.[5]

The one patient having post-prostatectomy retention of urine was found at autopsy to have an unsuspected vesical carcinoma, situated in the region of the prostatic orifice.

Again referring to the mortality rate (2.48 per cent) in this series of patients averaging 70 years of age, it is of interest to compare this figure with those of the American Experience Tables of Mortality which are used as a legal standard for actuarial computations by life insurance companies. According to this table, of 1,000 individuals living at the age of 70, slightly more than 6 per cent are expected to die from natural causes (that is, without any operation) before reaching the age of 71. Therefore, since the total of eight deaths in this series includes deaths from all causes, it is logical to conclude that this mortality rate of 2.48 per cent could be adjusted considerably lower, if it were possible to distinguish between deaths due to prostatectomy and deaths due to natural causes. This is rather a theoretical consideration, but serves to further emphasize the above statement that recent developments in prostatic surgery have served to reduce the mortality rate to almost nil.

CONCLUSIONS

1. Present day methods (preliminary preparation, sacral anesthesia and hemostasis) are such that prostatectomy has come to be a benign procedure with a negligible mortality rate (2.48 per cent in 323 cases).

2. Assuming proper attention to the above details, the chief hazard of prostatectomy is that of sudden, profuse and exsanguinating secondary hemorrhage occurring as late as the tenth post-operative day. This hemorrhage should be treated as an emergency measure and should be checked by mechanical means even though a secondary operation may be necessary. Under these circumstances, it is an error to wait and hope that this hemorrhage will cease.

3. As far as the late functional results are concerned, it is conservative to expect 82 per cent of "well" patients and 98 per cent well or mproved.

4. Urinary frequency, persistent to a greater or lesser degree following prostatectomy, even hough the cause of mechanical obstruction has been removed, is the chief reason why 16 per cent of these patients consider themselves merely "improved" rather than well.

5. With respect to late functional results, the chief hazards of the perineal operation are those of injury to the external bladder sphincter and to the rectal wall. It seems conservative to consider that these hazards are more than compensated for by the lower mortality rate following the perineal operation.

ACUTE POLIOMYELITIS*

Edward T. Evans, M.D., F.A.C.S.
Minneapolis

When the "Black Death" scourged the continent of Europe, people, panic-stricken, dumbly accepted the visitation without hope of survival if stricken, and with a fatalistic attitude which reflected their hopelessness.

Though anterior poliomyelitis existed as early as 2300 B. C., as evidenced by an Egyptian mummy described in 1927,[1] though the disease was recognized as an entity in 1734[2] and has been reported and described frequently prior to this century, it is only in the past two decades that it has assumed proportions so widespread as to focus public attention.

The disease is without question the most insidious, perhaps the most contagious, and certainly the most devastating in its manifestations, that medical science is called upon to combat—far exceeding the "Black Death" in its ultimate economic toll.

Rather than review its epidemiology, its history, and its recent epidemics elsewhere, let me call your attention to the fact that during the past five months Southwestern Minnesota has borne the brunt of a severe and virulent outbreak. To date some 172 cases have been directly or indirectly brought to my attention and it is my hope that I can, in the few minutes allotted to me, arm you with the most effective means of preventing loss of life and function.

The cause is unknown as yet—it is probably a filterable virus[3] or may perhaps be a pleomorphic streptococcus, as suggested by Rosenow. Its virulence varies in epidemics and in individual cases. It is most probably highly contagious and manifested in a widespread systemic form with, in a certain low proportion of cases, a subsequent central nervous system invasion. This invasion depends on certain poorly-understood factors, notably virulence and lowered meningeal resistance.

Its pathology, in the paralytic stage, is a round-cell infiltration deep in the nerve tissue, apparently blood-borne, with resultant death of nerve cells lying in the anterior horns of the spinal cord.

Its early diagnosis depends on the keenness of observation of the attending physician and its hopeful treatment depends on his early and fearless carrying out of the procedures I shall outline below.

Given a child, isolated or in the midst of an epidemic, who, following a comparatively mild respiratory or gastrointestinal upset, develops a headache with slightly rigid neck and painful back, together with a mild prostration and a rather wide-eyed, fearful, "follow-you around" stare—suspect poliomyelitis in its preparalytic stage, and proceed to corroborate your diagnosis and institute treatment.

To wait for further neurological signs, such as nerve tenderness or paralysis, is to court disaster and to label yourselves unworthy of your profession.

Take your microscope and counting-chamber to the child and perform a lumbar puncture immediately. Observe whether there is an increased intraspinal tension and immediately make your cell count. A polymorphonuclear increase, if epidemic spinal meningitis can be ruled out by a clear fluid, warrants a diagnosis of preparalytic anterior poliomyelitis.

And by this one procedure alone you have instituted one of our most effective means of treatment, as shown by the reports of Montgomery and Cole,[4] Aycock and Luther,[5] the Detroit epidemic, and a series of fifty-five cases of the author in 1925. Lumbar puncture probably decreases edema of the cord and this saves nerve cells otherwise doomed. It is effective also in many cases during the early paralytic stage.

Having established your diagnosis, you must devote all your attention to the prevention of paralysis.

Despite much research and many reports to the contrary, it is the consensus of opinion to date that no specific immune serum has been experimentally produced which is satisfactory. Until further corroborative evidence is brought forth, convalescent serum alone offers a real hope.

My statement requires some explanation. Flexner[6] showed that horse serum or other foreign protein serums, when injected in monkeys, so disturbed the meninges and choroid plexus by their reaction that the amount of virus necessary to produce symptoms of invasion was greatly reduced. He has even gone so far as to state that simple lumbar puncture may increase the permeability of the meninges and choroid plexus to the virus. And it is because of this action of foreign protein that I unhesitatingly decry the use of certain stock serums, even if convalescent serum is not obtainable. I have personally witnessed the rarest of all phenomena, a secondary invasion of the upper extremities two weeks after the invasion of the lower extremities had become stationary. This secondary invasion was coincident with the development of serum urticaria.

---

*Read before the Northern Minnesota Medical Association, Moorhead, Minnesota, September 19, 1930.

W. H. Kellogg[7] less than a year ago showed the fallacy of depending too much on clinical reports and urged the adoption of careful comparative studies and further laboratory research on this subject. Too many factors enter into the analysis of statistics, such as variation in virulence, unconscious reasons for selection of cases for treatment with one type of serum or another, accuracy of diagnosis, and prejudices inherent in the clinical observer.

Experimental data alone are unbiased. Monkeys are used and virucidal (that is, toxin-neutralizing) power must be demonstrated. Even so, the comparison of monkey and child is difficult because:

1. To give serum alternately requires cold-blooded courage, especially if one has any confidence in one form of treatment.

2. The child under treatment is already infected. The monkey is to be infected and the serum has proven to be more effective in preventing than in curing the disease after it is established.

Therefore, if the serum is to be used it should have proven virucidal powers. At present, convalescent human serum alone exhibits this neutralizing effect consistently and is proven experimentally effective.

While it is probable that most adults are immune, it has been shown by Flexner that normal serum has no protective value and the serum should be that of convalescent cases, and preferably within six months or a year of their attack, to insure the presence of antibodies in concentration.

If the whole blood is used it should be grouped if given intravenously. This is not necessary if given intramuscularly. Serum need not be grouped and is good for from six to ten months if kept properly.

The dosage recommended by Aycock and Luther is 20 c.c. intraspinally on successive days, though the dosage has not yet been established.

There is a controversy as to method of administration—whether intramuscular, intravenous, or intrathecal. I have already mentioned the effect of spinal puncture and shown its advantages as contrasted to its dangers. It is probable that a meningeal invasion already represents permeability of the meningeal barrier. Though some point out that the lesions are along blood vessels and argue that the serum should be so administered that the blood carries the immune bodies to the lesion, there are many reports indicating the advantages of intrathecal administration. It may be used in 10 c.c. doses intraveously followed by lumbar puncture and repeated in twelve hours intramuscularly followed by lumbar puncture somewhat as in the treatment of central nervous system syphilis. My own feeling is that much value accrues from the repeated lumbar punctures alone and that the intrathecal administration of serum is as safe, and certainly as effective, as the other means. Real value should be expected of the serum only in the preparalytic stages, as shown by the accompanying table compiled by the University of Manitoba Research Committee.

The report stated that in Group III the onset of paralysis was earlier than in Groups I and II, which raises the question as to possibly graver prognosis, and vice versa.

In conclusion, then, the case should be recognized early, diagnosed early, and treated fearlessly.

TABLE I (161 CASES)

	Number	Stage	Serum	Recovered	Residual Paralysis	Dead
I.	57	Preparalytic	One intramuscular dose	93%	7%	0
II.	17	Preparalytic	Two or more intramuscular doses	94%	6%	0
III.	33	Postparalytic	Various routes	22%	45%	33%
IV.	54	Postparalytic	Not given	26%	63%	11%

Note: Groups III and IV: No case made for serum after paralysis.

If paralysis has already occurred the same treatment should be instituted, especially the repeated lumbar punctures.

The orthopedic treatment begins immediately and is two-fold:

1. The prevention of tiring stimuli.
2. The prevention of deformity.

The first is accomplished by placing the patient in a quiet, comfortable room and supplying his every want so as to require the least expenditure of mental and physical effort on his part. E. D. Ebright,[8] of Kansas, even advocates a total body cast to preclude all external stimuli, though the author feels the attendant discomfort and resulting atrophy may defeat the end in view.

The second is accomplished by the early and adequate splinting of the affected parts in the optimum position of muscular relaxation. That this is essential is shown by a case at present under care at the University Hospital. Careful muscle tests showed involvement of both lower extremities and the left upper, so she was placed in double long leg plasters and left body, shoulder and arm spica. Two weeks later, despite the fact that no demonstrable paralysis was earlier found, the right deltoid had weakened because of its overuse and stretching in an adducted position. It also was then supported in an abduction plaster. The whole plaster splints are worn constantly for six or more weeks, till all tenderness subsides. I say constantly, because a month's recovery of tone may be lost in one stretching of an involved muscle. Thereafter, the splints are worn at all times for six months or more except when carefully removed for institution of graduated massage, careful muscle training or other rehabilitative measures.

Just what forms of splinting or bracing will be used in this late portion of the second stage will depend largely upon the individual case and the ingenuity or facilities of the attending physician. I cannot, however, stress too strongly this protective stage instituted as soon as the paralysis appears and continued for months until all possible recovery of the affected muscles is obtained. There still is considerable controversy on this matter between neurologists and orthopedists. This is due, I believe, to the neurologists considering nerve function alone, whereas the orthopedist is forced to consider muscle tone and function. We who see these patients with late deformities and weak, stretched muscles know that the muscle does not recover well unless held in relaxation till all irritation is past, and then is so weak that it must be carefully held during the re-education of nerve centers. Paradoxical as it seems, we have often seen returning muscle function long before the faradic reaction of a nerve returns. This was demonstrated conclusively in the nerve suture cases during the war. And again we have observed cases of infantile paralysis progressing nicely in braces, only to see them go on to irreparable loss of action on too early removal of braces. And we have never seen a deltoid muscle recover from paralysis if allowed any early stretching.

We who are constantly faced with the difficult task of reconstructing these patients beg that they be efficiently and carefully diagnosed, treated and protected in their earlier stages so that the economic and end-results may prove better in the future and a reflection of a high standard of professional skill.

IMPETIGO OR PEMPHIGUS NEONATORUM, WITH SPECIAL REFERENCE TO ETIOLOGY AND PROPHYLAXIS .

Robert A. Murray, M.D.
Duluth

Although impetigo or pemphigus has been a subject of common knowledge in the medical world for some time, it is only recently that its economic importance to maternity hospitals and to the doctors themselves has become impressive. The fact that so many hospitals are reluctant to divulge any information regarding their experience with this disease, bears witness to this fact.

In 1864 Telbury Fox first described and called attention to a form of vesicular eruption as seen in maternity departments. In 1891, Almquist showed the staphylococcus to be the infecting germ. In 1900 Matzenaver linked pemphigus and impetigo by the identity of the infecting organism. In 1911 Landsteiner was able to produce pemphigus lesions in a chimpanzee with material from a human lesion. Nothing new developed until 1917, when the disease seemed to change, became more virulent and appeared almost simultaneously in widespread epidemics throughout the country. The unprepared maternity wards were overwhelmed by the affliction with its high morbidity and mortality rate. No suitable explanation has been made for this universal outbreak, but the fact remains that we now have with us the menace of impetigo or pemphigus as a ghost, hovering over every maternity ward.

The disease is defined as an acute contagious inflammatory disease of the skin, in the newborn, characterized by the formation of papules and then vesicles which contain clear to opalescent fluid or pus.

Some writers use the terms impetigo and pemphigus interchangeably. Some tend to distinguish impetigo from pemphigus by the latter's greater virulence, earlier development of constitutional symptoms, greater morbidity, and poorer prognosis. Others distinguish pemphigus from the bullous exanthemata of many septic conditions and ally it to impetigo from a pathological and bacteriological standpoint.

Reed suggests grouping pemphigus, impetigo, exfoliative dermatitis, and multiple subcutaneous abscesses of the new-born as pyodermatitis neonatorum, in order to distinguish them from the same names applied to different types of lesions in older people.

Jordan makes a more specific pathological differentiation. He describes pemphigus as possibly beginning as a papule, but progressing rapidly to a bleb or bullous covering a circular fiery lesion, bright and shiny, with no ulceration, and suggesting more the appearance of a burn. These have no tendency to crust formation, discharge a clear to opalescent serum, with little increase in size, but more tendency to the formation of new lesions. These lesions are seldom on the face, never on the palmar surfaces, and occur mostly on covered areas, particularly in the skin folds, as in the axilla, groin, scalp, and under belly bands. That irritation is an important factor is shown by a predilection for moist and abrasive areas.

As impetigo he describes a red papule developing into an irregularly-shaped vesicle, flat, umbilicated, and containing a purulent fluid. There is a tendency to crust formation with the edges of the crust curling up. The lesion spreads eccentrically with irregular undermining vesicular edges. Removal of the crust leaves pus bathing an ulcerated surface. These lesions are predilected to exposed body parts, as the hands and face.

Jordan also makes a therapeutic distinction, stating that copper oleate and ammoniated mercury ointments are of value with impetigo, but have no effect on pemphigus.

In earlier epidemics the mortality was about 40 per cent, but in recent years since more attention has been paid to this condition, the mortality has been greatly reduced. Collins reports five deaths in a series of fifty cases in 1928. About 30 per cent of the infants exposed will develop lesions, and although the course is usually benign, with no effect on the infant's gain or health, in more virulent epidemics the mortality may reach 20 per cent. In transmission, healthy babies are affected as well as the weaklings. Where the umbilical cord becomes involved the outcome is usually fatal.

This condition should be diagnosed from congenital bullus syphilis, where bullæ are found on the palms and soles in infants who are constitutionally debilitated and from bullous eczema, which shows infiltration, weeping, itching, and non-pustular eczematous areas.

Exfoliative dermatitis is classed with impetigo by some writers but should be distinguished because of its fulminating course. Some cases beginning as pemphigus may progress to an exfoliative dermatitis and terminate fatally. Kohler reported a case of a normal baby developing a small bleb on the fifth day and dying on the twelfth day of exfoliative dermatitis.

Seeds reported a case of normal baby in good condition at birth who developed a purulent discharge of the right eye and vomited blackish-brown material on the second day. On the third day the temperature rose to 101 degrees F. A bullous impetigenous rash was noted on the fourth day. Pulmonary symptoms developed on the seventh day and the baby died on the tenth day. The clinical diagnosis was pemphigus neonatorum. Autopsy showed multiple lesions of the lungs from which staphylococci were isolated, and a gastric ulcer near the pyloric end of the stomach secondary to bacterial infection.

Different writers are at variance as to the organisms causing impetigo and pemphigus. Some believe the primary invader to be a skin streptococcus; others believe it to be staphylococcus aureus. The general opinion of most writers is that streptococci are the primary invaders in impetigo with staphylococci secondary, and that staphylococcus aureus is the sole invader in pemphigus.

In fifty-six cases Bolman found streptococci forty-three times, thirteen times in pure culture. He found staphylococcus aureus fifty-two times, twenty-one times in pure culture. He showed that the streptococcus alone could produce typical impetigo lesions. On direct smear from lesions the staphylococcus aureus appears as a Gram-positive diplococci, but upon culture media it assumes the typical staphylococcic clustering.

Placing the organisms on the skin of a newborn will be followed by the appearance of lesions in five to seven days. Olmstead has demonstrated that the contents of small pin-head sized papulo-pustules, which are clinically unimportant, contain many staphylococci. He states that oftentimes smears from impetigo lesions may be negative, and emphasizes that an infant once infected should not be returned to the nursery.

In some epidemics staphylococcus aureus has been cultured from cases of purulent conjunctivitis. Later reference will be made to such cases at this hospital. It is generally supposed that staphylococcus aureus may be carried in an apparently harmless form on various body regions of babies and adults. This disease is seldom found among babies born and cared for in the home. It is almost entirely an institutional infection.

Consideration of the transmission of this infection to the infants gives much material for discussion. The plausible theories are countless, but to establish these as facts becomes a problem more difficult to handle. No one can doubt that the doctor is sometimes responsible. He is in contact with infective material almost continually. His stethoscope has been used indiscriminately among his patients. The interne is also in contact with infective material through his routine duties.

The nurses carry a great part in the transmitting of this condition. As a group they are reluctant to admit any suspicious lesion because of the liability of losing time in their training, although they may be the cause of infections among babies under their care. Benians reported an epidemic in which many babies were infected in a short time. Investigation showed that the clean linen was being distributed by a person with a suppurating paronychia. Her removal was followed by a subsidence of the epidemic. He reports another epidemic which ended when one of the nurses, who was found to be suffering from a series of boils, was removed. Jordan proved two nurses to be carriers who did not have demonstrable lesions. Consideration must be given to the careless, indifferent nurse whose main interest is the completion of her duties rather than the proper execution of them.

The mother may herself be the source of the infection. One baby developed lesions on the back of the neck from a paronychial infection of the mother, and was the focus of a large epidemic in the nursery. It is acknowledged by all the writers that the genital tract of the mother may harbor pathogenic organisms. Jordan reports three mothers who developed pemphigus lesions over the sacrum following profuse lochial discharge. He reports one baby developing blebs thirty minutes post-partum, and two infants developing blebs three hours post-partum.

Waltart reported sixteen cases of infants, born with lesions, or who developed lesions shortly after birth. He reports a case of twins, one born with lesions, the other born without lesions and failing to develop any.

Nine cases are reported from the Wesley Memorial Hospital in 1925. In all the blebs leukocytes were found; five blebs were sterile and in one case a positive culture for staphylococcus aureus was obtained. One case was reported in more detail. This infant was born with fifteen pustules on a swollen scrotum. These pustules were yellow, from two to five millimeters in size, and some of the lesions showed retrograde changes. Twelve hours later pustules appeared on the hairy scalp; twenty-four hours later a subdermal fluid mass was noticed under the scalp; thirty-six hours later there appeared punctate yellow-headed pustules on the chest and abdomen. Cultures from the lesions on the scrotum showed a hemolytic streptococcus, but cultures from the other areas were negative. The mother of this infant gave a history of tonsilitis four weeks previous to delivery. This raises the question of infection going from the maternal to the fetal side through the placenta and giving rise to the disease intrauterine.

It seems plausible enough that infection may result from the vaginal or cervical secretions, where the interval between the rupture of the membranes and delivery is long enough. At this hospital, this year, an infant was born after a nineteen hour labor with a large cephalhematoma bounded from the head by an ecchymotic ring which later became necrotic. On the second day postpartum numerous punctate pustules appeared on this ring. On the third day small pustules were found on the body. Culture showed staphylococcus albus. These lesions healed in a few days under treatment with boric packs to the head, and calamine lotion to the body. Because of the short interval from birth to the development of these lesions it is most likely that this infection came from the genital tract and developed easily on the injured tissue.

Keho in his article acknowledges that the infective organism is contained in the vaginal secretion of some mothers, and that the infant may acquire the infection during birth.

Mayes and Ullian in a recent interesting article report a series of investigations, and show the high percentage of women presenting for delivery with pathogenic organisms harbored in the genital tract.

Indirect transmission must also be considered. It is quite evident that under the usual nursing regimen the infecting agent could be transferred from one mother to another, and thus from one baby to another. Through poor hygiene the mother may transfer infective material from her vaginal secretions to the infant's skin.

In most hospitals visitors are excluded from contact with the infants, but have full visiting privileges to see the mother. It is possible for the infection to be brought in by a visitor, such as the husband, and transferred indirectly to the infant at nursing time.

In the nursery the organism can be, and has been proven to be, harbored unsuspected among the various objects and equipment. Oftentimes oils, supposedly sterile, used for cleansing the babies are shown to be contaminated.

Irritation also plays a part. Many adult patients complain of the discomfort of irritation from hospital linen. The babies' clothing, laundered under the same process, is much more irritating to their more tender skin. Often the soap used in the babies' bath may be blamed because of high alkali content. That irritation does play a part is shown by the frequency of lesions developing at the sites of irritation and abrasion.

Olmstead blames the warm, moist skin from an overheated nursery and excessive clothing. In his experience, nursery epidemics are more frequent during the summer months. In contrast, at this hospital the infection predominates in the winter months.

In the average American hospital little is done in the nature of prophylaxis. The nursery supervisor should be governed by definite rules of prophylaxis as established by a group of staff physicians. It would be futile to expect or attempt a condition of surgical asepsis. To change gloves and gowns between each baby would incur too much expense to the hospital. The frequent scrubbing necessary would be too severe on the nurses' hands. However, with intelligent care and knowledge of the factors involved in the harboring and transmission of this infection, a condition of medical asepsis can be attained and the incidence and morbidity of this disease better controlled.

It is more difficult to control an extension of the infection in the general type of nursery where babies are cared for as a group, and where several nurses handle any of the babies indiscriminately. The babies should be handled as individually as possible and with an attempt at medical asepsis between them.

Several different nursery arrangements and routines as carried out in several hospitals with good results have been reported. Rulison reports the régime now used at the Sutter Hospital at Sacramento, California. The nursery is divided into sections, each accommodating six babies with their individual setups. These consist of the bassinette, a space for dressing and bathing the baby, and a shelf containing all the requisites for the baby's care. They have abandoned the spray bath and use individual bath units sterilized each day. The nursing system is so arranged that the same nurse takes care of three mothers and their three babies. These compose a unit. In the event that lesions appear, both the mother and baby are isolated under care of a separate nurse. No new patients are admitted into this unit until the other patients in this unit have been discharged and the unit cleaned.

This system carries with it a greater expense and necessitates a larger nursing staff, but Rulison states that since its institution only four suspicious cases have developed. In a training school a system in which the same nurse took care of mother and baby would be impractical for teaching purposes. It would be more feasible to divide the nursery into sections of about six babies each, with the nurses' schedule so arranged that the same series of nurses have only their group of babies and have nothing to do with the others. Also to divide the mothers into groups of the same number so that the mothers of a group of babies themselves compose a group under the care of a series of floor nurses who have no contact with other patients. I believe that the term group nursing is applied to this régime.

At regular intervals each section should undergo a thorough cleaning process, sterilizing as much as possible. In caring for the babies most writers advise that the gown be changed, and the hands scrubbed, or at least passed through an antiseptic solution, between each baby. Where a great number of babies must be cared for the time lost and the damage to the nurses' hands can be appreciated.

In many hospitals the nursery laundry is autoclaved and sent to a separate laundry where the clothing is washed by hand with a mild soap, and hung, preferably in the sun, to dry. This clothing is then delivered to the nursery in sterile packs. The purpose of this is to have the baby's clothing soft and sterile, containing as little chemical irritant as possible.

On admission to the hospital, as part of the preparation, the prospective mother should be given a complete bath, or, at least, a careful examination for suspicious lesions. Each day, postpartum, at bath time, this examination should be repeated. If any lesions develop, the mother and baby should be isolated. All babies and mothers who are placed in isolation should remain so until discharged. With this arrangement the infant population would be divided in two groups, namely, the isolated babies under the care of one nurse, separate from the general nursery, and the general group under one or more nurses as is practical for the number of babies and the subdivisions in that group.

Before beginning their period of training on the maternity floor all nurses should be carefully examined for lesions or conditions likely to incite such an infection. It should be made compulsory for any nurse to report any suspicious lesions on themselves as soon as noticed, and to remain away from the maternity floor until such condition is pronounced safe by a staff doctor. Caressing and kissing their charges, a practice which, although a great temptation, is too general among the nursery nurses, should be condemned. demned.

The nursery nurses should remove their gowns when they have finished with their charges and leave the nursery. When taking the babies to and from breast a gown should be worn which is to be replaced, before again coming for the babies, by a clean sterile gown. Nursery nurses should not visit out of the nursery in the same gown that is worn during the discharge of their duties.

There are many different routines for baby care in various hospitals. Some hospitals use olive oil for cleansing, but more hospitals are changing from this and using soap and water baths, either as a spray bath, or in individual bath tubs which are sterilized each day.

At the Minneapolis General Hospital, immediately after the delivery, the babe is taken to the nursery and given an olive oil bath. In the morning it is given a bath with water alone. Afterwards the baby gets its routine daily bath with a special soap made up by the hospital pharmacist. Suspicious cases are isolated and, with the mother, put under care of a separate nurse. A recent epidemic was shortened by daily sponging of all babies after their bath with saturated boric solution, and dusting with a powder composed of calomel and zinc oxide, each one part, and talc three parts. During this process the mouth and nose of the baby are covered with a gauze mask to prevent aspiration. At the University Hospital the baby after delivery remains untouched for six hours, then is given a spray bath using castile soap. Neither of these hospitals reports much unpleasant experience with this disease.

Keho reports the use of 1 per cent copper oleate in olive oil to remove the vernix. Kellert advises sponging after each bath with 50 per cent glycerine solution, which is supposed to exert an inhibitory influence on bacterial growth.

Collins suggests a daily bath with a weak solution of potassium permanganate, but this drug has the disadvantage of its staining qualities. Reed reports a series of cases after the injection of immunogen, made from staphylococcus aureus and albus cultures. Of forty-six cases injected during an epidemic, 80 per cent remained free from lesions; of twenty-seven cases not injected 80 per cent developed pustules.

There are several methods of treating this infection, and each has its advocates. The base of the lesions should be painted with some caustic solution such as 5 per cent copper sulphate or 5 per cent silver nitrate, only once, followed with continued application of some ointment such as copper oleate, 1–2 per cent, or ammoniated mercury 2–5 per cent. Stronger concentrations are too irritating and are no more efficacious. Holder advocates painting the region of the lesion with 2 per cent aqueous gentian violet, breaking the bleb and painting the base of the lesion with the same reagent.

In the past, at this hospital, immediately after delivery and daily, the baby was cleansed with sterile mazola oil. Recently that routine has been changed so that on the third day post-partum daily bathing with soap and water is instituted. If the baby develops suspicious lesions it is isolated under care of a separate nurse, but the mother remains under the regular nursing regime.

In a review of the obstetric charts for 1929, of 517 babies, twenty developed lesions of pemphigus or impetigo. The average time of appearance was five to seven days post partum. None of these cases were accompanied by any constitutional manifestations. The infection was still active at the time of the babies' discharge from the hospital. Sixteen babies developed purulent conjunctivitis, some of whom also had impetigo lesions. No cultures were taken, so the causative organism cannot be stated. Seven babies had lesions suspicious of pemphigus and were isolated, with no developments. All but two of these cases developed in November and December. Despite all efforts to eradicate it, this epidemic continued through May of this year. No explanation was found for the source, but since then, except for a few cases with several pinhead pustules from which staphylococcus albus was cultured, there have been no cases of impetigo.

In September of this year two cases with punctate pustular lesions appeared on the fifth day post partum. From these we cultured staphylococcus albus. Shortly after, two cases of frank impetigo developed. One appeared on the seventh day with one large pus-filled bullous on the left thumb, one on the right forefinger and several smaller lesions on the palms. The second baby developed lesions of the face, back of the neck, axilla and groin on the fifty day post partum. Cultures were made on blood agar hoping to find the streptococcus or staphylococcus aureus, but only staphylococcus albus was found. This indicates that further bacteriological study is needed to establish the relationship of the albus type of staphylococcus to this disease. This organism is the one most commonly found on our bodies, and, for that matter, in our general surroundings. Either there is a variation in virulence among the albus group or there is a variation in the defence reaction to its invasion.

The last case mentioned was treated with 50 per cent glycerine sponges after the bath, 1 per cent mercurochrome and 2 per cent ammoniated mercury ointment to the lesions, dusting with Mulford's preparation of bismuth-formie-iodide powder and general ultra violet ray administration. The results were very satisfactory.

SUMMARY

There is some distinction between impetigo and pemphigus from a bacteriological and pathological standpoint, but from the viewpoint of epidemiology they may be regarded as the same.

The mother is an important factor from an etiological standpoint in the transmission of this infection.

Group nursing, with individualization, as far as practical, is necessary in the nursery.

The institution of a prophylactic regime is important when the infection first appears in the nursery.

The nursery linen should be cared for in a separate laundry.

The vernix should be removed with copper oleate (1 per cent) or ammoniated mercury (2 per cent) in olive oil immediately and followed with routine daily bathing with mild soap and water.

An attitude of concealment is not a scientific one and combats any progress in determining the facts about this disease.

PROGNOSIS IN HEART DISEASE*

FREDRICK A. WILLIUS, M.D.
Rochester, Minnesota

ALMOST daily, some patient or his relative, or some physician, attempts to impose on the clinician the function of soothsayer. Most clinicians, I believe, strongly resent the implication.

Therefore, in arriving at a prognosis, disease should be analyzed in relation to its inception, its course, and its termination, in the light of symptoms and signs. Experience will permit application of quantitative values whenever they are possible, but it should impose the obligation to apply these values by the act of judgment.

It must ever be borne in mind that the art of medicine and the science of medicine are not synonymous terms that the sound clinician must possess the virtues of both. This is particularly true in cardiology, and the significance of individualization of patients cannot be over-emphasized, not only from the standpoint of prognosis but also from the standpoint of treatment.

Prognosis is not possible until the diagnosis of the disease has been accurately established. In addition to identification of the disease, it is necessary to obtain additional information with reference to factors and conditions that may influence not only the course of a given disease in general but also its course in an individual patient. Experience, recorded in the form of statistical data, gives valuable information. If data are completely recorded, and are sufficiently comprehensive in scope, they yield knowledge of what may be called the life cycle of disease. Such study of a disease necessarily deals with etiology, age of onset, course and duration, cause of death and age at death. The values obtained from a study of this nature are important, but they represent group ratios, and judgment is necessary in applying these values to the individual patient. The group is comprised of many individuals, who as individuals are in no way comparable, and would not be comparable even under conditions of normal health.

The obvious factors that may influence the life expectancy of a patient with heart disease are age, sex, heredity, occupation, etiology, type of lesion, mode of living, environment and intercurrent infections:

AGE

The time of life at which heart disease affects the patient as evidenced by the onset of symptoms, in relation to the time at which the etiologic factors entered, if this can be determined, has an important bearing on prognosis. Cardiac infections, for instance, are notoriously prevalent in younger persons, and are largely limited to the first three decades of life, when rheumatic fever, chorea, tonsillitis, and the acute exanthematic disorders are common. In the middle and later decades of life, a great number of patients have myocardial disease, such as results from hypertension, arteriosclerosis and hyperthyroidism. Syphilitic cardiovascular disease is most frequently encountered in the fourth and fifth decades, owing to the fact that about twenty years elapse from the time of the primary infection until the occurrence of symptoms and signs of circulatory disease.

The interval which elapses between the initial cardiac insult and the careful examination of the patient together with the institution of a correct, individualized remedial regimen are vital factors in determining the patient's expectation of life. In cardiology, as in many branches of medicine, early recognition and proper management of the disease are of unusual significance.

SEX

In an analysis of 4,059 cases of organic cardiac disease noted in The Mayo Clinic, the sex incidence was found to be equal. The general impression exists that heart disease is more prevalent in men than in women. This unquestionably is true in certain localities, in different kinds of practice, and in some forms of heart disease.

In a study of the influence of sex on the course of heart disease it was found that the average life expectancy of women is greater than that of men. This is undoubtedly due to the fact that women, as a group, are subjected less to occupational stress than are men, and that they more rapidly and completely adapt themselves to their physical handicap. It is interesting to speculate whether this observation will survive in the succeeding generations, owing to the fact that the so-called feminine emancipation and the World War has placed many women in arduous occupations previously held only by men. The influence of childbearing on women as a group unquestionably counterbalances the greater life expectancy to some extent. Infectious cardiac disease and hyperthyroidism are more prevalent in women, whereas hypertension, coronary disease, and syphilis are more prevalent among men.

HEREDITY

There has been considerable skepticism regarding the part heredity plays in the propagation of cardiovascular disease. Notwithstanding this skepticism, one who is in constant contact with patients who have these diseases becomes more and more impressed with the significance of the influence of heredity. I do not intend to imply that I believe that the disease itself is transmitted, but I am convinced that the tendency for the ultimate acquisition of cardiovascular disease is a heritage. I realize that the word tendency is used in a rather abstract manner, but its application here denotes the transmission of cardiovascular structures that lack the average qualities of resistance to the stresses and strains usual in an average life. The intermarriage of persons in whom cardiovascular disease may be present in one or in both, ultimately reflects the influence of the disease on their progeny, according to the law of Mendel. The detrimental influence is frequently carried further by subsequent intermarriages of descendants with others suffering from cardiovascular disease or descending from families in which such diseases are prevalent.

At this time, the average expectation of life in the United States is assumed to be about sixty-five years. This presupposes that the average cardiovascular system, regardless of the ultimate cause of death, is so constructed that it will continue to function when subjected to the ordinary stresses and strains of life for an average period of sixty-five years. In contrast to this are those persons in whom the heart, arteries and kidneys fail at a much earlier age. This is particularly true of patients who have hypertension, coronary sclerosis and the forms of arterial degeneration associated with such conditions. The part heredity plays in the obviously acquired diseases such as those resulting from infections, and so forth, undoubtedly is minimal.

A physician can readily convince himself regarding the rôle of heredity in connection with this disease by carefully inquiring into the causes of death in the patient's immediate and remote family. A striking example of the part heredity plays may be noted in the history of a patient who recently came under my observation. The patient was a man, thirty-six years of age, who presented himself for examination owing to the existence of severe cardiac failure. Analysis of this history was very interesting because it revealed that the paternal grandfather, the first member of the line in which the cause of death was known, died of apoplexy at the rather advanced age of seventy-two, seven years beyond the present accepted average, whereas the father, the representative of the succeeding generation, did not fare so well, and died of angina pectoris at the age of fifty-four years, nine years below the accepted average. The representative of the third generation, the patient, was a cripple from cardiovascular disease at the early age of thirty-six years, with a probable life expectancy of less than a year.

It is only reasonable to suppose that a structure, as important and as dynamic as the cardiovascular system, would have difficulty in surviving the stress and abuse to which it is subjected, even under ordinary conditions of existence, if its fundamental, endowed qualities are inferior. Physicians daily see patients who are identified as constitutionally inferior; yet these physicians seem to find it difficult to realize that this inferiority may not be generalized, but may be limited to various systems of the body.

OCCUPATION

Occupation is a vital factor in prognosis, and patients afflicted with heart disease, whose daily routine subjects them to strenuous physical stresses and strains, do not, as a rule, have a life expectancy comparable to that of other people performing lighter, more moderate duties. Whenever possible, it is desirable for patients suffering from heart disease to obtain sedentary employment, and the responsibility for such advice lies with the physician.

Another factor of significance is involved when advising changes. For instance, when the patients are operators of public vehicles, sudden death from acute heart failure would endanger the lives of many persons. The classification in this group would include railroad engineers, bus drivers, chauffeurs, aviators, and so forth.

It is becoming increasingly difficult for patients engaged in strenuous occupations to obtain sedentary employment. The extensive employment of women in business, in clerical lines as well as in industrial capacities, has created an enormous shortage of sedentary positions, so far as men are concerned. Many of the larger business and industrial organizations give preference to normal persons through the selective medium of physical examination, thereby further decreasing the chances of the person with cardiac disability to be self-supporting in occupations that are commensurate with his abilities.

Many of the larger cities, through public health agencies and welfare organizations, have become engaged in the problem of placing people with chronic heart disease in occupations suitable to their disability, and much has been accomplished already.

ETIOLOGY AND TYPE OF LESION

Life expectancy in the person with cardiac disease is largely dependent on the degree and extent of the injury to the cardiac musculature, and on the rate of progress of the pathologic process. Experience has shown that the mortality differs widely in various forms of heart disease. Prognosis depends mainly on the etiologic factor. In cases of diffuse myocardial disease, as exemplified by coronary and hypertensive heart disease, as a group the morbidity is highest, owing to the fact that, as a rule, these forms of disease occur in older persons, that the cardiac lesion so frequently is only a part of a more or less generalized pathologic process, and that the underlying disease tends to be progressive.

Endocardial valvular disease.—Chronic endocarditis, as emphasized in a previous paper, is the result of rheumatic fever or chorea. The prognosis in the initial attack or in the acute stage of the disease usually is good. Death rarely occurs except from associated or intercurrent disease. The ultimate outlook in endocarditis depends, in large measure, on the extent of the cardiac injury, that is, on the degree of associated myocardial and pericardial involvement, and on the care exercised in the subsequent management of the patient. As a group, death of persons with mitral disease occurs earlier than that of persons with aortic disease. When aortic and mitral disease coexist, the mortality averages approach those of mitral disease.

Acute bacterial endocarditis, which is usually the result of infection from *Streptococcus hemolyticus, Diplococcus pneumoniæ* (pneumococcus), staphylococcus and *Neisseria gonorrhea* (gonococcus) invariably is fatal within a period of from three to five weeks. As a rule, it is only an incident in a generalized infectious process.

Subacute bacterial endocarditis is probably always fatal. In a group of patients seen at The Mayo Clinic, none has recovered. Recoveries have been reported but, in view of more recent knowledge, the validity of the diagnosis in such cases is doubtful. It is now recognized that, from time to time, nonhemolytic streptococci are recovered from the blood stream of patients ill with rheumatic fever or with subsequent exacerbations of the disease. Under such conditions, recovery of bacteria by blood culture would probably indicate the presence of acute rheumatic endocarditis, and not the presence of the disease known as subacute bacterial endocarditis.

The average course of subacute bacterial endocarditis is eleven months; death occurs from gross visceral infarction, uremia, and the progressive inanition of infection and anemia.

Myocarditis.—As already stated, myocarditis, in the correct use of the term, exclusive of its occurrence in valvular disease, is a relatively rare condition, notwithstanding the frequency of such diagnosis. The prognosis here depends largely on the degree and extent of the injury to the muscle of the heart, and on the virulence and the persistence of the infecting organism. I have observed a small group of cases in which focal myocarditis occurred in the course of acute and subacute infectious arthritis, and in which there was an early and high mortality from the cardiac lesion. These cases represent diffuse myocardial disease; the focal areas often are confluent, and result in serious impairment of the function of the heart.

Pericarditis.—The significance of pericarditis depends chiefly on the infecting organism, its virulence, and the degree and extent of injury not only to the pericardium, but also to the other cardiac structures. Pericarditis may be classified as follows: (1) fibrinous, (2) rheumatic, (3) purulent, (4) adherent, and (5) tuberculous.

As a rule, the cardiac handicap resulting from simple fibrinous pericarditis is small and the prognosis is good unless the inflammatory process is recurrent and results in deformity. When effusion occurs, the seriousness of the condition is dependent on the quantity of fluid formed, its rate of formation, recognition of its presence, its removal before serious cardiovascular embarrassment occurs, and the type and virulence of the infecting microörganism.

The pericarditis of rheumatic fever is invariably only a part of the pancarditis, and, as a result of the extensive, associated cardiac injury is ultimately attended by a high mortality rate.

Purulent pericarditis frequently is rapidly fatal, as often it is but a manifestation of a severe, generalized infection. It may, however, arise by extension from a contiguous focus of suppuration, such as empyema within the thorax.

The prognosis in adherent pericarditis depends almost entirely on the degree of mechanical interference to which the heart is subjected, and to the rate at which the barriers develop. The process usually is insidious in its development, the heart responds gradually by hypertrophy, and functional adequacy is frequently maintained for many years.

Tuberculous pericarditis is essentially of two types, namely, the primary, in which the infection arises primarily in the pericardium, and the secondary, in which the invasion of the pericardium occurs from contiguous intrathoracic lesions of tuberculosis. The latter type is by far the more common, and unless the involvement is very extensive and unless secondary suppurative infection occurs, the prognosis is reasonably good. Under average conditions, it may be compared to the condition of pleural tuberculosis. However, the prognosis of primary tuberculous pericarditis is unfavorable, particularly when recurrent effusion occurs; the effusion frequently occurs in enormous quantities and is prone to accumulate very rapidly. Frequently, a fatal complication is extensive venous thrombosis involving the brachial vessels, undoubtedly in part the result of pressure and stasis.

Cardiovascular syphilis.—Early recognition and proper treatment are of primary importance in the prognosis of cadiovascular syphilis. In the early stage the lesion is limited to the outer layer of the aorta, gaining entrance by way of the small lymphatic vessels which accompany the vasa vasorum, and causing peri-aortitis. When invasion of the media and intima occurs, the process is often beyond control. As the inflammatory reaction of syphilis is productive, it soon leads to reparative fibrosis, producing deformities which have a profound influence on the cardiovascular mechanism. Of note among these cicatricial changes are those which involve the aortic valve leaflets and ring, causing aortic insufficiency, and those which produce atresia of the coronary orifice, thereby hampering the nutrition of the heart. It is probable that actual myocardial changes have occurred in all moderately advanced and advanced cases. The changes are hypertrophy in the case of aortic insufficiency, and myofibrosis in the case of atresia of the coronary orifice. Two fundamental lines of thought are advanced today with regard to cardiovascular syphilis. The first ascribes the failure of the muscle of the heart that ultimately occurs to purely mechanical effects, already discussed, and the second ascribes this failure to the actual existence of syphilitic myocarditis. The latter point of view has been supported by the occasional demonstration of spirochetes in the myocardium, although it is difficult to reconcile this idea with clinical and pathologic facts. The presence of gummas in the myocardium is a different matter, and irrevocably establishes the diagnosis of syphilitic myocarditis. Until evidence is offered which will lead to other conclusions the mechanical theory of myocardial injury must be generally accepted.

The prognosis in the early stage of cardiovascular syphilis is reasonably favorable, provided adequate and persistent treatment is instituted early. In the later stages, the outlook is uniformly grave, as progressive cardiac failure invariably occurs, even in spite of rigid treatment. Intensive treatment in the moderately advanced and advanced cases usually hurries the course of the disease, and may prove fatal soon after it is instituted. Such treatment should be avoided at all times.

The onset of congestive failure of the heart is the beginning of the end, in my experience; only two patients in the series seen at the clinic lived more than a year after its onset.

Diffuse, noninfectious myocardial disease.—Coronary sclerosis is one of the most important problems in cardiology at present. Angina pectoris occurs in about a third of the subjects, and undoubtedly represents the most serious form of the disease.

The early manifestations of the anginal syndrome are too often considered insignificant by the physician because the objective examination of the heart reveals little or no evidence of organic disease, and therefore the patient is permitted to carry on his usual work. The onset of retrosternal pain or discomfort and the occurrence of nocturnal dyspnea, particularly in patients of middle or later life, should always be considered an ominous sign until positively proved otherwise. The fact that the pain, origin and distribution are often atypical requires a knowledge of these possibilities in evaluating the condition of a patient whose complaints are not typical. John Hay very impressively expressed himself in the following words: "Prognosis is often at fault because the significance of the slight and early manifestations is misinterpreted. These minor anginas have certain characteristics which should enable them to be recognized for what they are, symptoms often unobtrusive, yet significant, and only yielding up their secret to careful cross-examination. They may be compared to a gesture, slight but ominous, and full of menace."

Acute occlusion of a coronary branch by embolism or thrombosis is one of the most serious catastrophes in cardiology, and it may occur in any case of coronary disease, even though the changes in the aorta are minimal. The immediate mortality is exceedingly high; at least half of the patients die at once or within a few hours. Those who survive the immediate attack may live for from several months to five or six years; death ultimately occurs from progressive myocardial failure or recurrent cardiac infarction.

Hypertensive heart disease.—The chief effect of hypertension on the heart is to cause myocardial hypertrophy, particularly of the left ventricle, due to increased work. As hypertrophy increases and dilatation supervenes, impairment of function occurs, which is manifested as heart failure. Associated coronary changes, as previously emphasized, modify the disease.

It is not always possible to foretell the manner in which a patient with hypertension will die. However, statistical study has shown that when the cardiac phase of the disease dominates, death usually occurs from heart failure. Prognosis in the individual case is extremely difficult; a serious prognosis given at the time of examination greatly embarrasses the physician if, several years later, he meets the patient, who appears to be still in fairly good condition. The onset of congestive failure usually warrants a grave estimate of the outcome, and the evident association of coronary disease obviously diminishes the expectation of life.

The heart in goiter.—The heart both in exophthalmic goiter and in hyperfunctioning adenomatous goiter is subjected to increased work as a result of the elevation of the basal metabolic rate. Irreparable cardiac injury in both diseases is unusual unless the course has been allowed to become protracted. The favorable prognosis that usually can be given in such cases is attributable to the fact that the disease of the thyroid gland is amenable to cure by operation.

MODE OF LIFE AND ENVIRONMENT

The patient's mode of life is molded by many influences; chief of these are his temperament, the habits he has developed, his financial status, which governs to a large extent the comforts and protections of life, his recreations, and so forth. Temperament is a very important consideration in heart disease, and is to a large degree a heritage. The intensive, dynamic, irrepressible person is an unfavorable subject to abide rigidly by the regimen prescribed, whereas his opposite, the phlegmatic, comfortable patient, readily adapts himself to such changes.

PHYSICAL SIGNS

The condition of the heart as elicited by careful physical examination gives very significant data regarding prognosis. The degree of efficiency and integrity of the heart invaded by disease is directly dependent on the condition of the myocardium. The size of the heart is an important prognostic sign, as marked enlargement, particularly when dilatation exceeds hypertrophy, frequently ushers in severe heart failure and death.

Murmurs are important signs in the diagnosis of the type of lesion, but do not deserve the emphasis they have received in the past. Not so long ago the presence of a murmur was considered a sufficient reason, regardless of the character, time, or situation, for diagnosing organic disease of the heart. Murmurs are frequently evanescent, particularly those accompanying increases in rate of circulation such as occur in anemia, hyperthyroidism and pyrexia.

The murmurs that are now recognized as being of greatest significance are those of mitral stenosis and aortic insufficiency. Prognosis does not depend on the murmur itself, but on the fact that the murmur in question indicates a valvular lesion, and the outlook is governed by the condition of the myocardium as influenced by the valvular lesion.

Gallop rhythm and heart tones that are distant and lack definition and differentiation are important signs, for they indicate a marked degree of myocardial fatigue.

Cardiac arrythmia of itself does not necessarily increase the seriousness of the prognosis, but it often occurs when heart disease is well advanced. This is true of auricular fibrillation, one of the most common and significant disorders of rhythm.

Premature contractions do not affect prognosis except as they occur in conjunction with serious disease of the heart. They are common in perfectly normal hearts. Pulsus alternans is always a very grave prognostic sign, usually is soon followed by death, and is indicative of marked impairment of cardiac function.

The prognosis with complete heart-block is, as a rule, unfavorable, particularly when associated with attacks of the Stokes-Adams type. The fact that most of these conditions are the result of coronary disease implies the existence of a pathologic process that is progressive in nature. Any disorder that may profoundly affect the brain, such as occurs during the Stokes-Adams seizures, is dangerous and may result in sudden death.

The prognosis of paroxysmal tachycardia depends chiefly on the type of tachycardia, and on whether or not associated organic cardiac disease exists. When associated heart disease is present, the prognosis is largely that of the underlying cardiac disease.

Electrocardiographic studies have revealed data of great prognostic significance not determinable by other means. This is particularly true of significant T wave negativity and bundle branch block. These facts, if no others could be found, would justify the use of the electrocardiograph in clinical medicine.

INTERCURRENT INFECTIONS

Intercurrent infections, either acute infections, episodes of one form or another, or foci of chronic infection, which exert influence during the course of cardiovascular disease, have unfavorable influences. Little usually can be done to avoid the acute infectious diseases, but evident foci of infection may be eradicated. The chief indication for this procedure is in the early stage of the disease, and not when the disease is so advanced that no reasonable chance for even temporary improvement exists.

Little is known regarding the etiology of arterial degeneration, and it is not beyond reasonable speculation that infection may play a vital part. It is therefore probably correct to eradicate foci even before the advent of actual disease.

TREATMENT

Prognosis in a large majority of cases is dependent on the adequate management of the patient. This must always be made an individual problem, for the cardiac status of similar types of disease varies greatly. There is little question but that the life expectancy of many patients can be distinctly increased by the institution and the maintenance of a proper regimen. This is not fully appreciated, and only too often little attention is given to a patient after he has temporarily recovered from an acute attack of cardiac failure.

FUNCTIONAL DISORDERS OF THE BOWEL*

R. S. Ylvisaker, M.D.
Fergus Falls, Minnesota

IT IS with a great deal of wholesome respect that one attempts the presentation of such a subject as this—functional disorders of the bowel. This attitude has as its chief source, perhaps, the gradually increasing mass of good literature on the subject which has appeared within the past few years. Certainly, after reading some of this literature, one is tempted to feel that, in our present knowledge, everything has been written on the subject that can be written. However, one's respect is not lessened either by the fact that probably more than 50 per cent of the patients who consult the average practitioner have as their main complaint symptoms to which no other label can be attached than that of a functional disorder of the bowel. Nor is this respect diminished by the fact that the functional gastrointestinal patient is usually the neurotic patient whose story is a long one, never repeated twice in the same way, and whose symptoms are multiple and vague.

The problem of the functional gastrointestinal patient is a difficult one, for it must be remembered that his complaints are as real as, and in some cases more severe than, those of a patient with far advanced carcinoma of the stomach. On the other hand, there is no more grateful patient than the functional patient who has found relief, or, in some cases, who has found only a satisfactory explanation for his symptoms. Thus, in many cases, at least, it will be found that the hours spent in carefully questioning, in thoroughly examining, in observing and finally in explaining the condition to, and reeducating such a patient are well worth while.

It is, of course, not the purpose of this paper to try to cover the entire field of functional bowel disorders. I shall try only to bring out a few points which I regard as important especially in regard to treatment.

As an introduction I would like to call attention to certain facts in the physiology of the intestinal tract. We are here concerned primarily with the physiology of the movements of the intestines and only secondarily with the process of digestion and absorption. In the small intestine there are three types of movement—the rhythmic segmentation movements which are localized rhythmic contractions of the circular muscle which knead the intestinal contents and spread them over the intestinal surface; the pendulum movements which are swaying movements in which the contents of a short loop of intestine are thrown from one end to the other; and lastly the peristaltic rushes—larger waves which may start anywhere in the small intestine and go short or long distances down the bowel. The latter usually start in the duodenum and usually go no farther than the ileo-cecal valve, but occasionally they continue on down the colon. Normally we do not feel these, but in disease conditions, especially diarrhea, they may be evidenced by "queer feelings, breaking out of sweats and fainting at the toilet" (Alvarez). Also, in exhausted and nervous conditions, we may become conscious of these waves. The colon has normally very sluggish movements. There is very little peristaltic activity. The material from the ileum is pushed into the cecum and ascending colon merely by the pressure of the material coming after it. From here the fecal material is transported to the pelvic colon by so-called mass movements. These occur only a few times a day—usually on arising in the morning and during or after each meal. When the pelvic colon becomes filled, the next mass movement carries the contents on into the rectum. This gives rise to the desire to defecate. In most people this occurs once daily, usually in the morning on arising or after breakfast, but this is by no means constant. The tonus of the circular muscle of the colon appears to act as a resistance to the mass movements.

There are two theories as to the origin of these muscular movements of the intestine. The older theory of Bayliss and Starling stated that they were chiefly the result of nervous impulses —the neurogenic theory. Recent work has tended to disprove this theory and show that the smooth muscle of the intestine has an inherent property of contracting rythmically, in fact that it may be entirely autonomic, the nervous mechanism acting merely as a regulator so that the various parts of the intestine may work in harmony. Alvarez has advanced his "gradient idea." According to this there is a gradual decrease in the inherent muscular activity and irritability and certain other factors from the duodenum on to the rectum. This, he says, accounts for the downward passage of food along the intestinal canal. An increase in the irritability at any point in the intestine may upset the downward gradient and disturb the passage of food along the intestine. Local spastic contraction may also be produced. This increase in irritability can be brought about by local irritation —by inflammations, by irritating foods and chemical poisons, and by nervous influences. It can be seen that this could result either in a diarrhea, or, if the spastic contractions are constant and prolonged, in an actual obstruction and thereby constipation. The fundamental process in either case is the same.

---

*Read before the annual meeting of the Northern Minnesota Medical Association, Moorhead, Minnesota, September 20, 1930.

As regards the physiology of digestion and absorption, there is one factor which seems to me to be important. Recent measurements of the length of the bowel in living human beings tend to show that previous measurements made on cadavers were much too long. In fact, it now seems proven that the intestine of man approaches very nearly those seen in carnivorous animals in which the length of the bowel is only from four to eight times the body length. In herbivorous animals the bowel length rises to from twenty-five to one hundred times the body length. In this connection it is interesting to note the observation made by Stefansson in his stay among the Eskimos. He found that these people have practically only fatty meats for food. In order to learn more about the effect of such a diet, Stefansson himself lived on an exclusive meat diet for two years, eating also, of course, the fat that came with the meat. He makes the statement that once he had become accustomed to his new diet he felt much better than he had before. Starling has the following further consideration to offer: "There is no doubt that many of the disorders of middle life may be put down to over-feeding and lack of muscular exercise, but there is just as much reason to ascribe these evils to the carbohydrates as to the proteins of the diet. Indeed, it has been found that for men leading a sedentary life a moderate protein and fat diet is more suitable than one consisting chiefly of carbohydrates. In this case the normal stimulation to oxidation of the foodstuffs, viz., muscular exercise, is absent, and the stimulating effect of proteins on metabolism, their specific dynamic action, useless when muscular work has to be performed, is under these conditions a real value to the organism." Farther on he states, "Overloading the intestines with carbohydrates in many individuals leads to abnormal fermentation, the production of gases, and general discomfort."

Time does not permit us to discuss the symptomatology and diagnosis of functional disorders of the bowel, but a few statements should be made in regard to diagnosis. Let me repeat here that the vague symptoms of nervous indigestion usually require a much more careful analysis than the definite symptoms of organic pathology. There are some patients in whom a diagnosis of a functional type of disorder can be made with a fair degree of certainty almost as soon as the patient begins to talk. Even these individuals require a careful examination if for no other purpose than to convince them that there is no organic disease present and that the condition is not a serious one. It must be remembered, too, that the neurotic patient can develop organic pathology. A very interesting case will serve to illustrate this. A man in the late fifties complained of a constant, dull pain in the midepigastrium which radiated straight through to the back. This had been present several months and had grown steadily worse. There was no relation to the taking of food nor to bowel movements. There had been some loss of strength. His previous health had been good and there were no other symptoms. The physical examination and laboratory and X-ray examinations were entirely normal except for a constant deformity of the duodenum with the barium meal. This certainly did not go with his type of distress. He was sent to the hospital for observation. During the period of observation the nurse in attendance complained repeatedly about the marked neurotic tendencies of the patient. Most of the day he would lie quietly in bed, but as soon as someone entered the room he would assume the position of one who was "doubled up" with pain. His conversation revolved almost entirely about his ailment. However because of the history of a recent onset in a man past middle life, the loss of strength, the duodenal deformity with no relief from careful ulcer management, an exploratory laparotomy was decided upon. An inoperable carcinoma of the pancreas was found.

As we come to the treatment of functional bowel disorders we look first for a classification to guide us. To classify these disturbances is, of course, not easy. Alvarez lists the functional types of indigestion according to the etiology and the outstanding symptoms as follows:

1. Fatigue neurosis.
2. Temperamental indigestion.
3. Anxiety neurosis.
4. Marital infelicity.
5. Nervous vomiting.
6. Psychopathy.
7. Constitutional inadequacy and asthenia.
8. Hypovarianism.
9. Enteroptosis (he no longer thinks that this causes symptoms).
10. Migraine.
11. Mucous colitis.
12. Intestinal allergy.
13. Constipation.
14. Flatulence.
15. Diarrhea.

This is probably the best grouping that we have to go by in arriving at the fundamental mental or emotional conflict and physical background at work in any individual case. It has struck me, however, that patients seeking relief for these functional disturbances fall rather naturally into a few larger classes somewhat as follows:

1. Those with constipation without other symptoms.
2. Those with symptoms which are due to the overuse of cathartics.
3. The high strung, nervous type, usually with a comparatively high degree of intelligence.
4. The weak-backed, asthenic, visceroptotic girl whose chief trouble is a general constitutional inadequacy and whose intelligence is usually somewhat below par.
5. The overweight individual of middle age or over with symptoms due to excess fermentation of starches.
6. The definitely psychopathic individual.

It is admitted that this classification is not all-inclusive. There is also considerable overlapping of the groups in many cases. But I think that the types pictured in each group will serve as fairly good models in treating most of the functional bowel cases who present themselves to the average practitioner. It should be repeated here that in those cases in which there is a mental or emotional conflict at the bottom of the trouble no good can be accomplished until that conflict has been settled.

Group 1.—The patients who come in complaining of constipation alone are comparatively rare. Now that the medical profession is coming to be properly educated in managing this type of case, it would be fortunate if more people would seek advice concerning this so that we might gradually re-educate people and undo the evil that has for years been done, not only in prescribing, but also in allowing people to use laxatives indiscriminately. Active propaganda is necessary in this respect. Provided organic obstruction to the bowel has been ruled out, and minor lesions about the anal canal have been treated, the best and simplest advice to give these patients is not to meddle, but allow nature to take care of itself. It should be explained to them that there is a great variation among people in the frequency with which they must empty their bowel. Some people can go three, four and five days without a bowel movement and feel no ill effects. They should be instructed, however, to yield promptly to the desire to defecate. Other than this, they should forget that they have a bowel.

Group 2.—The patients in this group may also complain only of constipation. Further questioning will bring out the history of the frequent use of cathartics and coarse foods and the presence of a certain amount of abdominal distress. These patients show the symptoms and findings of the "spastic" or "irritable" bowel in its simplest form. Their symptoms vary usually according to the length of time they have been subject to the cathartic habit. There may be only mild griping pains after the taking of laxatives. On the other hand, the patient may complain of many symptoms, including pain, which may be localized anywhere along the course of the colon and which is usually described as cramps or gas pains, burning pain in the epigastrium, fullness in the epigastrium, queer feelings often described as "an all gone feeling," the desire to defecate when the rectum is empty, passage of small quantities of mucus in the stool, flatulence, loss of appetite, nausea, vomiting, and sometimes general symptoms such as headache, dizziness and lassitude. The characteristic feature about the abdominal symptoms is their relationship to defecation. A good bowel movement usually relieves some or all of the symptoms temporarily. The treatment depends on the severity of the symptoms. Mild symptoms will usually be relieved as soon as the irritant laxative or food has been stopped, provided the condition has been explained to the patient and the fallacy of the use of laxatives and coarse foods pointed out. Patients with moderately severe symptoms will require more careful management. They should be given a bland, low residue diet. If possible, they should rest for an hour after each meal with a hot water bottle to the abdomen. If the bowels do not move for two or three days, a small quantity—2 ounces—of olive oil may be injected into the rectum at bedtime to be retained over night. An attempt should be made to move the bowels the next morning. If this is unsuccessful, a half pint of plain tap water or physiologic saline solution may be injected to start the bowel movement. Antispasmodic drugs are often helpful, such as the calcium salts—pure grades of calcium carbonate and calcium phosphate. If pain is prominent, small doses of extract of belladonna may be added to the calcium salts. During the course of treatment, the physician should frequently observe the character of the stools at the same time as he is taking his patient's mind off this subject as much as possible. It should be remembered that a small, hard, marble-like stool has the same significance as a mushy or liquid stool, indicating an overactive or spastic bowel. Severe cases should be treated the same as a severe diarrhea, put to bed, started out on scalded milk and hot gruels every two hours, hot wet packs to the abdomen every alternate hour and it may be necessary to add bismuth and larger doses of belladonna or opium to quiet the bowel. As the condition of the patient and the character of the stool improves, bland foods should be added and the patient soon put on the more moderate management previously outlined. It is necessary to warn the patient that some time may be needed in readjusting the bowel and to reassure him that no harm is done by the small, infrequent, hard stools.

Group 3.—This group includes many of the hardest working and most keenly intelligent people that we meet. Their chief trouble is that they drive on and on carrying the burden and doing the work of several average people until finally they crack under the strain. Once we are able to "get under their skin," allow for some of their eccentricities and explain to their satisfaction the cause of their present condition, they become some of our most pleasant patients. Their abdominal symptoms are essentially those of the irritable bowel with a tendency to be more vague than those listed in the cathartic habit group. In many, a chronic cathartic habit is superimposed. There may be constipation or diarrhea. The cases of so-called mucous colitis usually come under this group. In addition, there is the general nervous and muscular tension often resulting in insomnia and other difficulties. The main therapeutic indication is for rest, physical and mental, as far away from their pet worries as it is possible to get them. To begin with, sleep and relaxation should be induced by means of sedatives, the simpler ones like the three bromides and luminal being the best. These can later be tapered off as the patient improves. While the patient is on the rest cure, it will usually be necessary to treat his abdominal symptoms. This is best done by giving a bland diet and prescribing the other measures used in the treatment of the spastic bowel. The hot abdominal packs will be found especially useful in relaxing the tense patient and often is the main factor in inducing sleep. Light, general massage and ultraviolet radiation treatments are also beneficial in improving muscular tone and building up the patient's resistance.

Group 4.—There are many men as well as women who fall into this group, but we are best acquainted with the young lady mentioned so that she can be used as type. She is probably the most trying of our patients. Her symptoms are due mainly to such a lowering of her nervous threshold that most of the sensations which come in to her central nervous system are immediately referred out again to some organ or organs in the form of pain, hot and cold flushes, paresthesias and what not. Her symptoms are therefore varied and vague and not necessarily referred to the bowel although the mass of efferent nervous stimuli set free must certainly upset the downward gradient of forces in the bowel and produce conflicting muscular contractions and therefore intestinal symptoms. She is usually also below par physically and is therefore more subject than most of us to all human ailments. Not only that, but often she is somewhat lacking in mentality and so unable to cope with the problems of life. I recently saw just such a patient. On top of it all she was married to man twice her age and lived with her aged parents-in-law. It is not necessary for me to describe the result. In treating these people it is best to explain to the family at least that we cannot expect a cure. The most that we can hope to do is to try to build up their resistance and so ward off some of their physical ailments. Occasionally they can be educated to live fairly comfortably with their nervous troubles. In carrying out the treatment, it is probably best to put them to bed away from the family. The mass of nervous stimuli which bother them should be cut down as much as possible by means of sedatives and a bland diet. The latter should have a high caloric value and, to begin with, it may be necessary to force the feeding by having the nurse feed the patient. Ultra-violet radiation is important. In many cases small doses of thyroid extract are of value in speeding up the general metabolism.

Group 5.—The quotation from Starling previously cited characterizes this group well. The excessive fermentation of carbohydrates is, however, seen in others besides the overweight individual of middle age. In fact, in my opinion, the outstanding dietary sin of today is the excessive use of carbohydrate foods, and I believe that recent physiologic studies support this view. As the difficulty that these people have is an excessive fermentation of carbohydrates, their chief symptom is flatulence. In severe cases there has resulted also a considerable degree of bowel irritability with its symptoms. General symptoms such as headache, dizziness, nervous irritability and muscular weakness are common. The chief indication for treatment is the withdrawal of carbohydrate foods as far as possible. If the symptoms of bowel irritability are marked, the diet should at first have a low residue. Alvarez believes that the chief cause of excess fermentation is an excess of undigestible cellulose in the diet. Some fruits and vegetables may later be gradually added. The permanent diet should consist mainly of milk, cream, butter, eggs, meat, and fruits and vegetables. Potatoes, bread, and cereals should be used in moderation. Pastries, rich foods, preserves and hot breads should especially be avoided. A generous amount of daily exercise is necessary to help burn up the glucose as it is absorbed. Calcium salts greatly help the bowel irritability.

Group 6.—The group of definitely psychopathic individuals with abdominal symptoms may be a real diagnostic problem, and this is the only reason for including them here. Once the diagnosis is made, the only treatment is to turn them over to a competent psychiatrist. They bring out the importance of carefully going into the family history for a hereditary background for insanity and into the patient's previous history for evidences of peculiarities of conduct. If the diagnosis is missed, they come to be a real nemesis for the practitioner, as ordinary forms of treatment are worse than useless for their fixed notions.

SUMMARY

1. Attention is called to certain facts in the physiology of the movements of the intestines and of digestion and absorption of food. Particular emphasis is laid on the fact that certain influences may bring about an increase in irritability anywhere along the intestinal tract, resulting in either a diarrhea or a constipation, and also on the fact that recent physiological studies point to an error in the present day tendencies toward high carbohydrate diets.

2. The necessity for careful study of the so-called neurotic patient is brought out.

3. The classification of Alvarez is cited and a simplified classification is offered, based mainly on types of patients familiar to most practitioners. A brief outline of the management of each of the groups mentioned is given.

BENIGN POLYPS OF THE COLON AND THEIR RELATION TO CANCER*

Harold E. Hullsiek, M.D., F.A.C.S.
Saint Paul

CANCER claims one out of twelve in the human race. One out of every thirty lethal cancers occurs in the rectum. Carcinoma of the intestinal tract comprises 12 per cent of all cancers of the body, and of these, 65 per cent are in the rectum. Lockhart-Mummery, after a study of two hundred cases of carcinoma of the rectum, believes that the most important predisposing cause, apart from age, is the presence of benign adenomata. In a large majority of his cases in which a segment of bowel had been resected for carcinoma, associated adenomata were present. Verse asserts that most gastro-intestinal cancers arise from simple adenomata, themselves the result of inflammatory hyperplasia.

In a series of one hundred and twenty-seven cases of multiple polyposis collected from the literature by the author in 1928, the known malignancy incidence was 34.6 per cent. An additional thirty-one of these patients died after having suffered symptoms which were very suggestive of malignancy, so that it is reasonable to suppose that the index is considerably higher than the figures show. Jones says, in speaking of polyps, that they are, ". . . a condition we have come more and more to believe of great importance, of even greater importance than carcinoma itself, for polyps frequently become carcinoma, and proper treatment before they become malignant means permanent cure." Yeoman says, in speaking of single, benign polyps, "Unless thoroughly removed at the base they are likely to recur and are prone to malignant degeneration." Nowhere, according to Ewing, can more clearly be demonstrated the logical transition from simple inflammatory hyperplasia to tumors which are morphologically, pathologically, and clinically adenomata and carcinomata. The foregoing remarks and quotations should be sufficient to emphasize the necessity for a keen appreciation of the potential dangers of benign tumors of the bowel.

A tumor, Ewing says, is an autonomous new-growth of tissue, and may be classified according to one of three plans, regional, etiological, and histological. The tumors under consideration are obviously best discussed from the histological standpoint, yet at times they must also be considered as to their morphological features.

In a collection of 46,379 cases of rectal disease of all types, benign tumors were found in 554 instances. Dewis collected in 1904 reports of 219 cases of benign tumors of the intestinal tract, on each of which a microscopic diagnosis was available. Leichenstern collected from the literature 128 intestinal polypi. Of the total 247 cases in the two series, 243 tumors were in the rectum and colon, and 202 were adenomata. We are able to state with a reasonable degree of assurance that approximately 50 per cent of all the benign growths of the intestinal tract are in the rectum, hence well within reach of the examining finger. The moral is obvious.

We find in the colon angiomata, fibromata, myomata, lipomata, adenomata, and papillomata or villous tumors, the latter being extremely rare. The distribution of the various types is shown in the accompanying table of Dewis' and Leichenstern's 347 cases. An inspection of this table shows a preponderance of adenomata in almost all parts of the intestinal tract, there being a total of 255 adenomata in 347 cases.

TABLE I

	Angioma and Papilloma	Fibroma	Myoma	Lipoma	Adenoma	Total
Duodenum	0	0	3	6	6	15
Jejunum	0	0	2	4	8	14
Ileum	0	2	11	7	37	57
Appendix	0	0	1	0	2	3
Cecum	0	0	3	2	6	11
Colon	0	1	5	10	40	56
Rectum	2	2	10	6	156	176
Small bowel	1	0	1	2	0	4
Intestine (undefined)		0	4	7	0	11
Total	3	5	40	44	255	347

Analysis of Dewis' 219 cases from a slightly different angle shows similar results.

---

*From the Miller Clinic. Presented before the Northern Minnesota Medical Association, Moorhead, Minnesota, September 19, 1930.

Table ii

	Total No.	Per cent	Rectum	Per cent
Angioma	3	1.3	2	66
Fibroma	5	2.2	2	40
Myoma	40	18.2	10	25
Lipoma	44	20.0	6	14
Adenoma	127	57.9	81	64

Here we find that 57.9 per cent of the 219 tumors reported by Dewis were adenomata, and 64 per cent of these were situated in the rectum. The distribution of adenomata in comparison with all other forms explains the interest surrounding them in a consideration of benign tumors of the colon.

Table iii

	Small gut Per cent	Large gut Per cent	Rectum Per cent
Adenoma	11	25.2	63.8
All other forms	48	27.1	24.8

The adenomata will be seen to increase in frequency in direct proportion as we proceed distally through the gastro-intestinal tract. In the small bowel other tumors are four times as common; in the large gut they occur with the same frequency as all other forms combined.

Adenomatous polyps are important not only because of their frequent occurrence, but are of primary interest for the same reason that any benign tumor attracts more than passing attention—its potentiality of becoming malignant. In the author's collected series of multiple adenomata there was a known malignancy of 34 per cent while in Soper's series the figure was 43 per cent. In the author's series of personal cases of single polyps, there were, in twenty-five cases, six that were cancerous.

New-growths in the colon may or may not be polypoid in shape. The word polyp has a purely morphological application and bears no relation to histological character. A polyp is merely a new-growth with a pedicle and may be an adenoma, fibroma, or a lipoma, and may be benign or malignant. The numerous attempts at a classification of polyps, either clinical or pathological, have been unsatisfactory. Mummery groups the adenomatous polyps of the colon as follows:

1. True multiple adenomata.
2. Multiple polyps associated with hyperplastic tuberculosis.
3. Polyps accompanying old strictures of the rectum.
4. Polypoid conditions resulting from ulcerative colitis.

It will be seen that the latter three groups in the above classification have definite associated irritative lesions. The relation of polyps to mucous membrane irritation is well known.

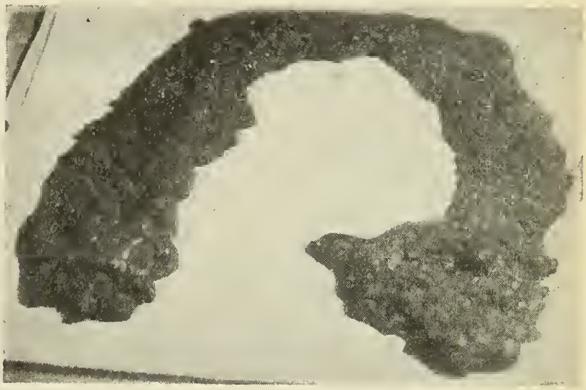

Fig. 1. Fresh specimen of colon showing multiple polyposis, removed from father.

In discussing adenomata it should be recalled that there are two apparently distinct types which, although histologically similar, are different in distribution, in the production of symptoms, in prognosis, and many other ways.

Erdmann and Morris in 1925 suggested a clinical instead of a pathological grouping, which seems very adequate. Single or scattered polyps, sometimes the obvious result of irritation, again with no discoverable associated etiologic lesion, sometimes quiescent and discovered incidentally, at other times producing violent symptoms necessitating immediate intervention, constitute the class now known as the acquired type. Clinically this type of adenoma occurs most frequently in children, but is also often seen in adults. In my own series the ages ran from three to seventy-one years.

As has been said, 63 per cent of the adenomata of the intestinal tract are located in the rectum. The single polypoid adenoma may be found immediately inside the anal canal, in the ampulla of the rectum, at the recto-sigmoid, or in the sigmoid itself. Palpable pedunculated tumors in the anal canal are more likely to prove to be hemorrhoids which have undergone inflammatory change. If situated low down the tumor sooner or later develops a sufficiently long pedicle that permits it to protrude during defecation. A frequent site for single polyps is the anterior wall of the rectum at the sharp fold marking the recto-sigmoid.

The adenomatous polyp is in some cases not a true adenoma but merely a polyp covered with more or less normal mucosa. Macroscopically it is bright red, glistening, mulberry-like, and varies in size from 2 to 3 centimeters in diameter to that of a walnut. Tumors the size of an orange have been reported. These tumors bleed easily and thus exhibit as one of their early symptoms a streaking of blood in the stool. The pedicle may be short and thick, or slender and several inches in length. Microscopically they are seen to spring from the mucosa of the intestine and have a connective tissue stalk covered with glandular epithelium showing a hyperplasia. Ewing calls the development of adenomatous polyps "inflammatory adenoid hyperplasia."

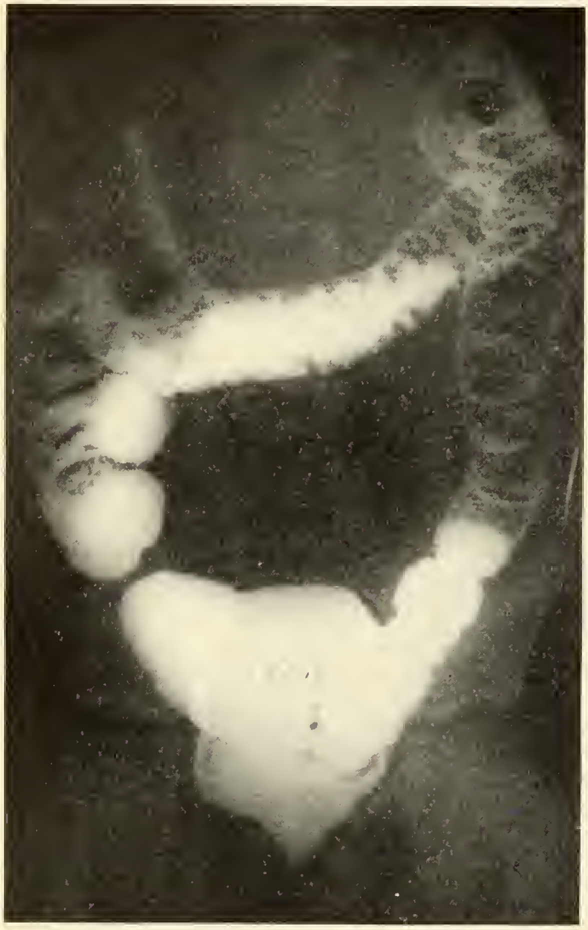

Fig. 2. Roentgenogram of ten-year-old son, showing multiple polyposis.

In considering the question of malignancy in single polyps we must remember that these tumors are usually promptly removed as soon as they are discovered, thus ending once and for all any chance of their becoming malignant. In my series of single polyps there was a malignant degeneration in 24 per cent. From the fact that benign, solitary adenomata are frequently seen in children, one would feel that the incidence of carcinoma of the rectum in childhood should be higher than is actually the case, if these tumors have such a high malignancy index. Unfortunately we have no information as to the length of time these tumors may be present before cancerous change occurs, but apparently it may be years.

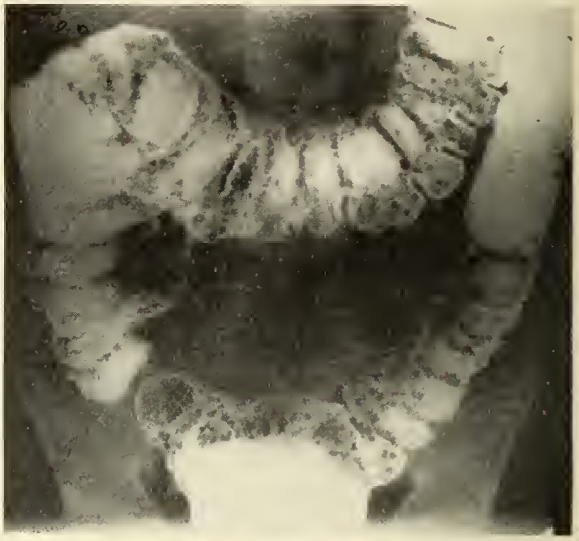

Fig. 3. Same as Figure 2.

The symptoms vary from none at all to slight signs in the case of small tumors, to occasional bleeding, and, depending on the size and location, tenesmus, and a sense of incomplete defacation, to obstruction or intussusception in the case of large ones. The following table shows the symptoms in the author's series.

TABLE IV

No symptoms	5
Bleeding only	7
Bleeding and irritation	1
Bleeding and discharge	2
Bleeding and prolapse	4
Prolapse only	1
Bloody diarrhea	2
Sense of incomplete evacuation	1
Pain referred to bladder	1
Obstruction	1

Bleeding is one of the earliest symptoms of carcinoma of the rectum. Buie says, "Bleeding is the most constant sign of malignant disease of the lower colon. Bleeding is probably one of its earlier manifestations." It will be seen from the above table that bleeding occurred as one of the symptoms in sixteen out of twenty-five patients. Jones says, regarding polyps: "Blood is also present with polyps of the colon or rectum, a condition which we have come more and more to believe to be of great importance, of greater importance than carcinoma itself, for polyps frequently become carcinoma, and proper treatment before they become malignant means permanent cure."

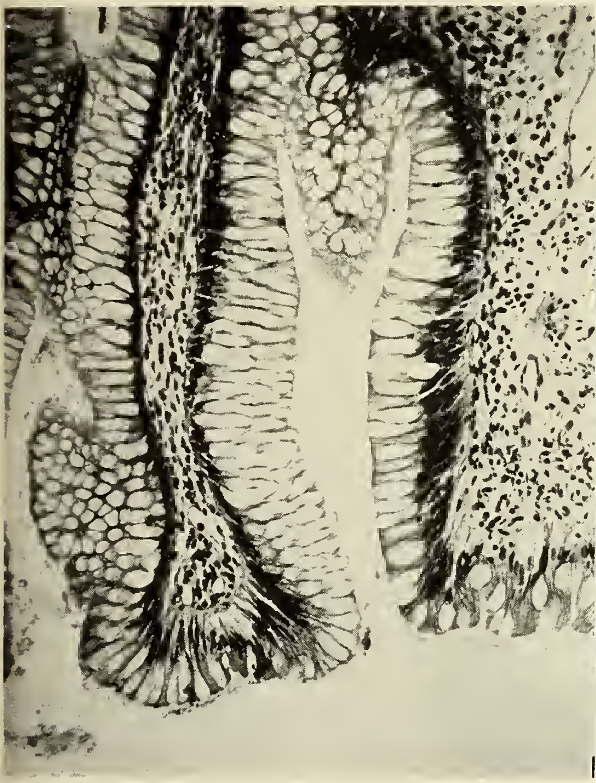

Fig. 4. Benign polyp, high power, from father.

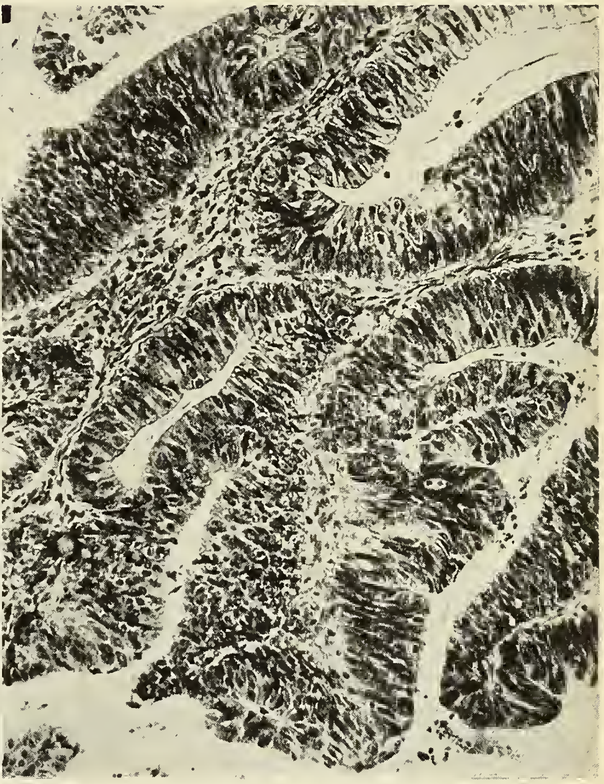

Fig. 5. Malignant polyp, high power, from father.

Single adenomatous polyps should be considered as pre-malignant growths and as such should be promptly and completely removed when found. If the growth is low in the anal canal or rectum the sphincter may be relaxed with novocaine, after which the polyp may be prolapsed and the pedicle ligated. If high in the rectum or in the sigmoid they may be removed through the proctoscope by means of a snare. Certain precautions should be used in snaring tumors which are situated above the lowest valve of Houston, since at this level the peritoneal reflection occurs and too full a bite may result in an opening into the peritoneal cavity. Ordinarily, even with a cold snare, the bleeding is only slight but may occasionally be troublesome. One of my cases bled sufficiently to fill the rectum with clots several times and ceased only when the stump of the pedicle was fulgurated. No difficulty of this sort has occurred since using the diathermy snare.

In the case of congenital, multiple polyposis we have an entirely different picture from that of a single polyp. In this type we find the mucosa of the bowel replaced by hundreds of small polypoid adenomata. Luschka estimated the number in his case at 10,000. This form usually makes itself evident in childhood or early youth and rarely has a discoverable associated etiologic lesion. This disease has a distinct familial tendency and a malignancy index of from 40 to 50 per cent. This is the true multiple, adolescent, congenital polyposis, and to this type only should the term multiple polyposis be applied. Scattered single polypi do not necessarily indicate a multiple polyposis.

The average age in 127 cases of multiple polyposis was 30.9 years, with an average duration of symptoms of over 10 years. As to familial tendencies we may again quote Lockhart-Mummery. He says: "It appears to be a hereditary condition, as it can be traced through several generations, and the curious thing is that in such families a large proportion of individuals die at a comparatively early age from cancer of the bowel." Dukes reports one family in which his patient had multiple polyposis, while his mother, six uncles and aunts, and a grandfather died of cancer of the bowel. I have a patient at present under my care with this condition, a boy ten years of age (Figs. 1-5). His father and uncle died of multiple polyposis, verified at autopsy, while the grandfather died of cancer of the rectum.

In a consideration of any surgical procedure in cases of multiple polyposis it immediately becomes evident that the type of operation selected is governed by certain features of each individual case. We must consider the question of malignancy, which is often present already when the case is first seen, extent of involvement, general condition of the patient, and the technical ability and surgical experience of the operator. The treatment is by no means standardized, and is in general very unsatisfactory. Ileosigmoidostomy followed by colectomy has been successfully done three or four times for the relief of this condition. Coffey successfully performed a total colectomy on a woman with the disease. Appendicostomy has failed entirely in some cases, while in others it apparently afforded relief while the opening persisted, only to have the tumors spring forth with renewed vigor when the appendicostomy was closed. Radium and X-ray therapy have been employed, but with disappointing results. Ileostomy or cecostomy with irrigations has resulted in at least a temporary disappearance of the tumors. Erdman says: "One may sum up the present status of treatment of this condition by saying that the only method which holds out any hope for cure in the disseminated variety is one imposing upon the operator great technical difficulties, upon the patient great danger, and upon both the possibility that a successful operation may prove fruitless because the operator has been unable to determine accurately the extent of the process, and has, therefore, left behind areas capable of transmitting all the original potentialities of the disease."

The cause of death in multiple polyposis is in 50 per cent of the cases due to carcinoma. The remainder die from anemia, sepsis, exhaustion, and starvation. Fortunately it is a comparatively uncommon condition.

Little has been said in this paper concerning the other benign tumors of the colon because of their comparative infrequency of occurrence as well as proneness to remain benign. The adenomata represent a problem which we must face as one of the things to be recognized in our struggle with cancer. Early recognition and early operation are of paramount importance in the treatment of this dread disease, and an appreciation of the menace of the commoner benign polyps of the colon will lead to earlier diagnosis of cancer, a larger number of operable cases, and a consequent lowering of mortality.

DIAGNOSIS AND TREATMENT OF PILONIDAL SINUS*

James Kerr Anderson, A.B., M.D.
Assistant in Surgery, University of Minnesota
Minneapolis

THE finding of a pilonidal sinus in a surgical practice is a fairly common occurrence, more so in fact than is generally thought. The fact that this anomaly is listed under many different names is confusing. In reviewing most of the available literature on the subject, the following names have been attached to it: coccygeal, sacrococcygeal or sacral fistula, sinus or dimple; post-anal dimple, fistula or fissure; posterior umbilicus; post-sacral or sequestration dermoid; pilonidal sinus or cyst.

The comparative infrequency of this type of sinus as compared with other types about the anal region and the essential treatment of them, particularly when they become infected, warrants a review of the subject. The condition was first described in 1867 by J. M. Warren in Surgical Observations, published in Boston. The name pilonidal sinus literally means a nest of hair and this often properly describes the condition, although in many cases no hair is found. Just how this sinus in the posterior median line is formed is a matter of some controversy and many theories and anatomical explanations are forthcoming. The majority do feel that the condition is congenital and the result of a faulty coalescence of the cutaneous covering of the back during early embryonic life or, stated differently, an imperfect approximation of the lateral halves of the fetus involving only the integument. Mummery states that the sinus is only an exaggeration of the post-anal dimple and that they are really sequestration dermoids due to the skin being shut off from the external surface. Drueck believes that the sinus does not connect with the other structures but is a subcutaneous tract lined by epithelium and ending blindly. Bookman, using the name sacro-coccygeal sinus, says that it is the result of the breaking down of a sacro-coccygeal cyst. Bevan reports forty cases and states that it is congenital and consists of a bud of epithelium turned under the external integument. Warren in the original article advances the theory that the cause of the trouble is a reversed hair follicle and that the turned in hair as it continues to grow pulls its hole in after it. Wendelstadt, quoted by Morter, advances the following theory: "The inferior end of the spinal cord is the last portion of the cord to lose its connection with the skin; as the sacrum fuses it pinches off this connection and the skin becomes attached by fibrous tissue at this point to the posterior surface of the sacrum. As adult life approaches, fat and soft parts grow and lift the skin further away from the bone. The attached part is thus drawn into a dimple or sinus." Streeter, of the Carnegie Institute, examined histologically a specimen removed by Dr. Stone and feels that it is special downgrowth of epithelium, originating from the true skin and not the medullary groove, none of the elements of the true skin being fully developed, the hair being thin and fine and the pigment scanty like lanugo. Herman and Toureux, also quoted by Morter, showed that after separation of the spinal cord from the superficial tissues a process of epithelial tubules persist for a time at the site of the previous connection of the neural axis with the skin, forming a vestigial remnant which normally disappears. When atrophy fails to take place a pilonidal sinus may develop. If included ectoderm is completely surrounded it is called a cyst; if partially so a sinus or fossa.

These sinuses are congenital and are the result of an infolding of the epithelium. Whether this is an active downgrowth or at a certain point the epithelium remains fixed to the underlying tissues and subsequent growth of the intervening tissues deepens the dimple we cannot say. We do not feel that it has any connection with the neural canal. These sinus cases, however, rarely come to the physician unless they become infected, which results in all the symptoms of an acute inflammatory process over the sacrum. Sweat, hair, debris plus trauma, lead to inflammation which terminates in abscess, fistula or the formation of a true cyst. The location renders them susceptible to trauma and it is difficult to keep them scrupulously clean. Proximity to the rectum also may be a factor in infection.

---

*Read before the Northern Minnesota Medical Association, Moorhead, Minn., September 19, 1930.

As to the diagnosis the location over the sacrococcygeal region, superficial to the sacrum, and the characteristic appearance of the "stitch hole" opening, usually single and several inches above the anus should make one suspicious. In case hair is protruding from the opening, the diagnosis is certain; but this is not always present. Upon closer examination the sinus tract will be found in a large majority of cases to extend upward rather than toward the anus, parallel to the long axis of the body and no connection will be found with the anus or rectum, variation in depth and diameter being marked. One author states that the sinus may surround the rectum but never enters it, seldom however deviating from the midline. It may break into the rectum following inflammation and plugging of the tract. There may be several external openings but usually one will be found to be lined with skin and the others with granulation tissue and have ragged ulcerated orifices, these acting as channels for drainage when the original tract becomes obstructed. Multiple openings all connect with the original sinus. The great majority of these cases are reported to have been found in those with excessive pilous growth and the large percentage in males. Stone reports sixty-one cases, 84 per cent occurring in males and all white, in spite of the large colored population in Baltimore. Gant reports a series of eighty cases with 80 per cent males. Another author reports a series of eighty-one with 66 per cent males. In twenty-nine of these eighty-one, hair was found in the sinus or protruding from it. The sinus may remain undetected for some time or until injury or infection occurs and draws attention to that part and indicates surgical interference. Many cases give the history of having been operated upon several times with a later recurrence. This is due to the fact that all the lining of the sinus tract was not removed. Ninety-five per cent of the cases are infected when first seen and this alone usually brings them to the physician. The sinus is rarely found in children as it is not looked for and infection has not yet taken place. It may be found with a spina bifida and Moise reports a pilonidal sinus which connected with the spinal cord through a spina bifida occulta and resulted in a staphylococcic meningitis. Ripley and Thompson also report a case in a child extending to and communicating with the arachnoid space which also resulted in a staphylococcic meningitis and death. These two cases would suggest a medullary origin of these sinuses. Connection with the canal, however, is rare. Brams suggests that all cases should have a lipiodol injection to determine the extent, location and possible connection with the canal. Some patients give a familial history of these sinuses.

Infected pilonidal sinus should be differentiated from osteomyelitis, tuberculosis or lues of the coccyx or sacrum by X-ray examination and the fact that there is no bone felt with the probe; from anal or rectal fistulæ by the type of opening, direction and lining of the tract and character of the discharge, whether fecal or not; from ordinary pyogenic processes by the presence of epithelial lining in the abscess cavity and the tract, and the lack of proper healing. If there is a tuft of hair extending out of the opening the diagnosis is certain. Plugged sebaceous follicles may simulate the condition, but these are very shallow. Teratoma, fetal implantations, traumatic dermoids, implanatation cysts, have to be differentiated by gross and microscopic examination.

Treatment.—The recognition of this condition and its pathology is most important in order that the proper type of treatment may be applied and a permanent cure effected. Radical excision of the whole infected area when not too large is the surest method. In cases with large abscess formation, drainage, followed, when inflammation has subsided, by complete excision of all the sinus tracts and their lining as well as all cyst tissue, has in our hands been successful. Various other methods have been employed and cures reported in a few cases. Unless the surgical pathology is recognized, embarrassment may result. The tracts and epithelial lining must be removed completely or the wound will not heal. We have found it best to let the wound granulate in, the only objection to this being the time required. Lahey of Boston moves over a flap of skin and fat and so allows granulation to take place in tissue that is known to be healthy. The excised wound may be sewed up tightly but in our cases this proved satisfactory in only two cases.

In case the sinus opens into the rectum it is necessary, as in the treatment of other types of fistulæ, to divide the sphincter, as well as to remove the sinus lining. Maillard reports one case treated successfully by the galvanic current without pain or incapacitating the patient. If the case is seen before infection has taken place various destructive agents may be tried, as nitric acid, silver nitrate, carbolic acid, actual cautery, etc. Tuttle in his textbook states that occasionally pulling out the hairs and cauterizing the tract with silver nitrate will result in obliteration. Crookall reports a method of treatment in which he scalps the skin over the diseased area, cleans out the tract and packs with pure powdered silver nitrate and leaves this several days, when the entire lining membrane comes away and the wound begins to granulate; this method to be used when the accepted surgical treatment cannot be carried out. When severe infection or abscess is present, incision is indicated, to be followed when the acute stage has subsided by radical treatment as mentioned. Indication that all cyst or sinus wall has not been removed will be given by continued drainage and lack of healing in certain parts of the base or sides of the wound or by the finding of small openings in the base or sides which will admit a probe. At the time of operation one may be certain that all the cyst tissue has been removed but several days later a small grayish area may be seen in one or more spots which indicates incomplete removal and requires further excision to insure healing. Morter reports thirteen cases of infected sinus in which, following radical excision and partial primary closure followed with Dakin's solution, 85 per cent of the wounds healed without becoming infected. Morter also states that failure in treating these cases is due to too early operation following incision and drainage for the acute stage, accidental opening of the tract during operation causing contamination. Simply cleaning out the tract when uninfected may be sufficient, but after infection palliative methods are useless.

Anesthetic.—Gas, oxygen, local block or spinal anesthesia are usually used, much depending on the choice of the patient. Epidural anesthesia may be used, but owing to the fact that there is infected tissue in the region which may be penetrated it is not wise. The possibility of deformity of the bony structures also contradicts it.

Dr. W. A. Fansler and myself have operated upon twenty cases of infected pilonidal sinus, using radical excision or removal of the tract and cyst tissue. Eighteen healed by granulation in an average of nine and a half weeks; two by first intention, following closure of the wound. Seventy-five per cent of the patients were males. Fifty per cent gave a history of having been previously operated upon. The sinus ran upward from the external opening in all but four cases: two ran to the left and two to the right. Trauma directed the attention to the sinus or caused some change in it in two cases. Single "stitch hole" openings were the rule, multiple ones being found in six and in these cases the secondary openings were not typical and represented avenues for drainage. Nearly all sinuses opened into large abscess cavities. None was encountered opening into the rectum and it was necessary to remove the coccyx in only one instance.

SUMMARY

1. The location of abscess, swelling or soreness over the sacro-coccygeal region should always arouse suspicion of the presence of a pilonidal sinus.
2. Cases are rarely seen except when infected.
3. The exact etiology of pilonidal sinus has not been determined but we feel that it is an embryonic defect involving only the epithelial covering.
4. Hair was found in the sinuses or protruding from them in a few instances in our series but 50 per cent had been previously operated upon.
5. X-ray of the region should be carried out and the injection of an opaque medium is recommended.
6. Radical excision of the entire area if possible or of the cyst lining after drainage is the treatment of choice.
7. Primary suture is occasionally successful.

TYPICAL CASE REPORTS

W. S. O., a male, aged 31, has had for the past four or five years an abscess over the sacrum which would either rupture or require incision. This has healed and then broken open five or six times, the last time two months ago, since when it has continued to drain.

Examination showed a large inflammatory area over the sacrum with a stitch hole epithelial lined opening over the coccygeal junction which is partially occluded owing to the swelling. A probe could be introduced for two inches upward over the sacrum. At operation the inflammatory mass was excised in toto, the wound healing by granulation in six weeks. When examined the sinus was found to divide into two lateral ones, each lined with a greyish membrane which also lined the abscess cavity. Gas-ether anesthesia was used.

R. N., a male, aged 35, had had a soreness and swelling above the rectum which had been incised and has been draining off and on for about one year.

Examination shows three stitch hole openings in the posterior mid-line one to two inches above the anus. There is quite an area of swelling and redness about one and one-half inches in diameter and there is a purulent discharge from the uppermost opening. A probe introduced into this opening comes out the lower ones.

At operation the entire mass was excised in toto under spinal anesthesia. Long hairs were found in the cyst sac. Healing occurred by granulation in six weeks.

E. S., a female, aged 20, a very hairy type, about one year ago noted swelling and some tenderness over the sacrum. This was thought to be a boil and a poultice was used, which caused the swelling to break. Following this it apparently healed, but about one week before coming to us she again noted swelling and soreness which this time evacuated itself and has continued to drain blood-stained pus copiously. Her physician thinking that she had some bone disease referred her to an orthopedist, who recognized the condition and she was referred to us. Examination revealed two small openings over the sacro-coccygeal articulation, both discharging pus. The upper opening was surrounded by excessive granulation tissue. A probe was introduced into the sinus tract upward for about 10 cm. and an area of induration the size of one's hand was present over the sacrum. X-ray revealed no bone disease. Radical operation was performed and the entire mass excised. The wound healed by granulation.

F. G., a female, aged 23, had had a pilonidal sinus for five years, which occasionally would swell and discharge pus, had been operated upon three times for radical cure, but had failed to completely heal.

Examination showed an inflammatory area over the sacrum with several small openings which admitted a probe in all directions.

At operation the entire area was excised. Practically all of the cyst tissue was found in the wound. Healing occurred by granulation in three months. Spinal anesthesia was used.

DETECTION AND TREATMENT OF RESPIRATORY INFECTIONS AMONG UNIVERSITY STUDENTS

E. Hanson, M.D., and J. Arthur Myers, M.D.
Minneapolis

SINCE 1920 special interest and attention have been devoted to the prevention and treatment of all types of respiratory infections among the students of the University of Minnesota. A paper was published in this journal in April, 1925, reporting the first four years of the work done in the chest clinic of the Students' Health Service. At that time 803 students had reported for special chest examinations.

From September, 1924, to September, 1928, the second four year period of the chest clinic's existence, 747 students reported for examination. The registration of students entering the University is not considered complete until each student has undergone a physical examination. All students who present unusual chest findings at this time are referred to the chest clinic for special study. Students enrolled in the university who present themselves for treatment of colds and other upper respiratory infections whose conditions seem to have become at all chronic are encouraged to report for special chest examinations. In a lesser number of instances students who are aware of the danger to themselves of massive exposure to respiratory infections report for examination at regular intervals. This is especially true of student nurses and medical students whose work presents the added hazard of more frequent exposure to tuberculosis. The one great object of the chest clinic is the early detection of any chest condition which may become chronic. And to this end the coöperation of every other department of the Student Health Service and usually of the patient concerned has been freely given.

When a student applies for examination, a history is taken with special reference to exposure to tuberculosis, previous respiratory disturbances, onset of the present trouble, etc.

In Table 1 we have tabulated the diseases from which the 747 students had, according to their statements, previously suffered.

From this table it will be observed that influenza, pneumonia, "dry pleurisy" and bronchitis occurred most frequently. Of the 747 patients, thirty-seven gave a history of having had tuberculosis. Of this group only seven gave histories of a definite known exposure to this disease, while sixty-seven others had lived with members of their own families who had active tuberculosis, but had themselves never become ill from the disease.

Table 1

FREQUENCY OF RESPIRATORY DISEASES AS INDICATED BY PAST HISTORY

Influenza	399
Pneumonia	150
"Dry pleurisy" (Fibrinous)	151
"Wet pleurisy" (Effusion)	32
Bronchitis	202
Tuberculosis	37
Bronchial Asthma and Hay Fever	43
Empyema	14
Gassed	5
Bronchiectasis	1
Total Number of Students Examined	747

In the majority of cases, students present themselves with two or more definite symptoms of respiratory disease. Only those who had adopted for themselves the plan of periodic "check-ups" were at times symptom-free. Table 2 indicates the frequency with which each symtom or complaint occurred.

Table 2

FREQUENCY OF COMPLAINTS AS REPORTED BY STUDENTS

Cough	444
Expectoration	361
Chest pains	309
Loss of weight	181
General malaise	317
Shortness of breath	271
Night sweats	50
Fever	7
Hemoptysis	33
Bloody sputum (streaking)	40
Hoarseness	181
Fistula	9
Mastoid	1
Ear abscess	1
Cervical abscess	1
Total number of cases	747

On physical examination, the findings in the vast majority of cases were normal. This examination was limited to the cervical and thoracic regions, and the findings elicited by the methods of inspection, palpation, percussion and auscultation were as follows: axillary lymph node enlargements 51; retractions of chest wall 10; lagging of chest wall 8; impaired resonance 11; rigidity 4; impaired or abnormal voice conduction 28; breath sounds impaired 6; and râles 90.

With but few exceptions, stereoscopic X-ray films were made of the chest. They were always found of great help in diagnosis and aided materially in determining the extent of involvement, if any.

Tuberculin tests were applied routinely. The sputum was examined microscopically in all cases where any indication existed for so doing.

With the history, physical signs, symptoms and laboratory findings noted, the diagnoses made in these 747 cases are indicated in Table 3.

TABLE 3

CONDITIONS FOUND IN 747 STUDENTS GIVEN SPECIAL CHEST EXAMINATIONS

Negative	444
Diagnosis undetermined	35
Acute bronchitis	49
Chronic bronchitis	28
Acute upper respiratory infection	20
Pleurisy with effusion	6
Proved tuberculous pleurisy	3
Healed empyema	4
Chronic fibrous pleurisy	30
Pneumothorax—spontaneous	5
Bronchial asthma	10
Bronchiectasis	16
Tuberculous lesions demonstrated by X-ray	106
Cervical adenitis	3
Tuberculosis of bone (hip)	2
Unresolved pneumonia	2
Pneumonia	2

From this table it will be seen that in the great majority of cases, 444, negative diagnoses are made. These were students who came in with less aggravated symptoms or with only histories of massive exposure to tuberculosis. Their X-ray studies showed no pathology and result of laboratory work in general was not indicative of any active disease. These students were encouraged to continue their regular curricular activities. In many cases their fear of physical examinations was overcome and we believe that many of them will be convinced of the value of periodic examinations which should aid materially in detecting and checking the inroads of insidious chronic respiratory conditions.

Acute bronchitis was diagnosed in forty cases. Treatment here consisted of bed rest, hot applications, abundant fluids with a light easily digested diet; sedatives were administered whenever necessary for cough.

In 106 cases the X-ray studies showed the presence of tuberculosis. Of these, forty-one gave positive clinical evidences of the disease. In forty-five of the cases detected by X-ray films, the tuberculous lesions appeared to be well under control. Three cases were diagnosed as cervical adenitis, and tuberculosis followed pneumonia in four cases. There were also three students who came in with pleurisy with effusion, tuberculous in origin, and one case of sacro-iliac tuberculous disease. Of the pulmonary cases, thirty-five were diagnosed as clinical fibroid tuberculosis. The pulmonary lesions were bilateral in thirty cases and eleven showed cavity formation.

Of the forty-one cases of clinical tuberculosis, nine gave histories of massive exposure to the disease; that is, one or more deaths had occurred in the patient's own family, a sister, brother or parent having died or been under prolonged treatment of this condition. It is interesting to note that ninety other students who showed no clinical evidence of tuberculosis gave a history of similar massive exposure. Of the above forty-one cases, ten had been diagnosed as tuberculous at some previous examination.

In the clinical cases the symptoms present at the time of examination were as follows: persistent cough 39; expectoration 25; dull indefinite chest pains 25; general malaise 30; loss of weight (from 5 to 20 pounds) 21; dyspnea 20; afternoon temperature elevation 2; night sweats 6; blood streaked sputum 4; hemorrhage 7. Of the total number of cases (747), 4.4 per cent gave histories of frank hemorrhage as compared to 17 per cent in the cases (41) of clinical tuberculosis.

In all cases of active clinical tuberculosis students were advised to discontinue their activities and seek treatment at once.

A number of times during the last eight years students have reported for examinations who were found to have frank pulmonary tuberculosis which appeared to be of long standing. Cavities were present. Tubercle bacilli were abundant in the sputum; yet our examination was the first that had ever been made. Some of these students had reached the junior or senior years in the university. They had been mingling with other university students. They were unsuspected cases of tuberculosis. Yet they were perhaps more dangerous to their fellow students than the girls and boys who had previously known of their disease, and were employing the usual measures to protect others.

From such findings we are firmly convinced that dangers from tuberculosis will lurk among the students of the universities of this country just as long as we fail to make compulsory, careful examinations for tuberculosis of all entering students, and sufficiently frequent periodic examinations during their stay in the university.

The ordinary physical examination has never sufficed in the detection of tuberculosis. Before we knew how inadequate it is, perhaps we were justified in continuing its practice.

Observations of recent years have shown that there are two phases of an examination which must always be used if we are to detect the greatest possible number of cases of tuberculosis. These are the tuberculin test and the X-ray examination. The ideal procedure, therefore, would be to apply the intracutaneous test to every girl and boy entering a university. Nearly all who have ever been infected with tubercle bacilli will react positively to this test. Those who react positively should have X-ray film examinations. It is true that a simple fluoroscopic examination will detect those lesions of a more massive nature, but many of the minimal lesions will remain undiagnosed unless X-ray films are made.

A considerable number of entering freshmen will react negatively to the tuberculin test, but during their university months and years they may be exposed to tuberculosis. Therefore, at least every year—and better every six months—these negative reactors should be retested with tuberculin. All who become positive reactors should have X-ray films made of their chests. If disease is detected, whatever treatment is indicated should be administered. If disease is not detected, they should be placed on the list for frequent periodic examinations.

Tuberculin testing is a very inexpensive procedure. Fluoroscopic examinations do not cost much. X-ray films are relatively expensive, but inasmuch as a single film of the chest gives one such valuable information, it should never be omitted. In many universities at the present time it is a physical impossibility to make films of all positive tuberculin reactors. The funds are not available. In such institutions it may be possible to appropriate enough money to make films of all the students in one school. The best coöperation is usually secured from the students of the medical school, the school of nursing or the school of dentistry. As time passes and the procedure becomes more popular, and funds more readily available for this purpose, the entire university can be included in the program. Such a procedure may be likened to the application of a fine tooth comb to the student body in an attempt to comb out as many as possible of the cases of tuberculosis. Those found to have this disease will be rendered a great service—one which far more than justifies the expense. But perhaps greater than this, the entire student body will have been rendered a service and given an opportunity to live and work in a university environment free from the dangers of exposure to tuberculosis.

ORGANIZED CARE OF PATIENTS WITH ACUTE RHEUMATIC ENDOCARDITIS*

M. J. SHAPIRO, M.D.
Minneapolis

EACH year on re-opening the Minneapolis School Heart Clinic we are invariably met with a group of children who have just recovered from an attack of rheumatic fever and who have been referred to the clinic for proper disposition. This is a most serious situation and I feel the sense of responsibility as the problem is placed directly on me for disposal. Now, what are the possible methods of handling these children, methods which are at hand at the present time?

1. They can be sent home to be kept in bed until we are sure that all signs of activity are gone.
2. We can have their tonsils removed.
3. We can send them to Dowling School, where they will get the same treatment that the orthopedic cripples are receiving. This school was built originally to provide treatment for orthopedic cripples alone. About five years ago I obtained consent from the Board of Education to send a number of cardiac children to Dowling and I have had the opportunity of following them since. The children are conveyed to and from school in buses; all exercises are strictly supervised. Each child has a nap in school, he is served a hot meal at noon and is given sunlight treatment, either natural or artificial.
4. We can send them back to their regular schools, thereby evading the problem entirely.

In order to give you some idea of the situation as it presents itself I have gone over our records for this year at the Lymanhurst Heart Clinic. Amongst the sixty children examined since the beginning of the present school term, seventeen had their first attack of rheumatic fever some time in 1930, seven of them having been ill during April, 1930. Ten of the seventeen were found to have not only clinical evidence of cardiac involvement but cardiac enlargement on X-ray examination. The remaining seven were found negative to both clinical and X-ray examination and were diagnosed as potential heart disease. I might say here that a systolic murmur at the apex in a rheumatic child is not considered due to mitral disease unless the X-ray shows enlargement of the heart. It is most interesting to note that nine of these seventeen children had had their tonsils removed before this first attack of rheumatic fever, three still had their tonsils, and five had had their tonsils removed since the attack of the disease.

As I have said, I have had the opportunity of studying a group of children of this type at Dowling School during the past five years. I have been very much impressed with the fact that these children continue to show signs of rheumatic activity for months and years after the acute infection has subsided. Most of them continue to run a more or less constant low grade fever up to 100 F.; they are troubled with frequent attacks of pain in one or more joints; they complain of muscular pain; tachycardia is often present, even with an almost normal temperature; they are often pale and their weight fluctuates from time to time. While these signs of activity are going on it has been my rather disheartening experience to note constant and progressive changes in the heart. I have observed a number of children who have entered Dowling School when they showed merely evidence of a simple mitral regurgitation and as time went on I could hear first the development of the characteristic diastolic murmur of mitral stenosis and months later a suggestion of a diastolic whiff along the left border of the sternum which invariably after a period of time finally developed into a definite diastolic murmur of aortic regurgitation. Later still one could hear the systolic murmur of aortic stenosis appearing over the aortic area and still later the peripheral signs of aortic regurgitation. I have also had the unpleasant experience of watching five of this group develop subacute bacterial endocarditis while they were attending school. I have been able to predict in many instances, from the signs of rheumatic acitivity, which children would eventually show signs of increasing crippling of the heart.

---

*From the Department of Medicine, University of Minnesota, Minneapolis, and Lymanhurst School Heart Clinic. Read before the Central Interurban Clinical Club, December 6, 1930.

Confronted with such a situation it is apparent that it is impractical to attempt to send these children to their homes to be kept in bed. Anyone who has had any experience with this problem knows that most of these children come from the poorest homes. Then again they do not feel nor do they look sick. It is impossible to keep them in bed all alone for long periods of time. They become morbid and restless and this sort of reaction defeats the purpose of keeping them in bed. Then, too, they are prevented from attending school during this period and it is well understood that these children need education more than any other group, as it will be necessary for them to use their heads rather than their muscles as they grow older. Sending them home for bed rest is, then, not feasible; they might better go back to school and continue to develop the almost inevitable valvular heart disease.

How about taking out their tonsils with the hope of protecting them from repeated attacks and especially to protect their hearts? I believe it has now been conclusively proven that tonsillectomy does not protect the heart in rheumatic fever and in most instances does not protect against subsequent attacks. As I have shown from the short résumé of these seventeen new cases, nine of these children had had their tonsils removed, some of them four to five years previously, and still they developed rheumatic fever. In Kaiser's recent article in which he reported a study on some 2,000 children, he showed that children who had had their tonsils removed ten years previously were not protected against rheumatic fever nor against rheumatic heart disease. I believe that tonsils should be removed no more often in rheumatic children than in any other group. Tonsillectomy, then, does not solve our problem.

I believe I have already indicated that sending these children to a school like Dowling does not give us a satisfactory result. This type of treatment has been provided for rheumatic children in many cities in this country. It is my opinion that schools of this kind are suitable for children with advanced cardiac disease who are unable to attend regular school because of lack of physical reserve. These schools could also be used to enter children who had just returned from a prolonged stay in bed. Children could be admitted to such a school for a semester to try them out to determine whether or not there were still any signs of continued activity. But this type of school is not satisfactory for the recent post-rheumatic child. It does not protect him. It permits activity to go on and allows continued crippling of the heart.

Not having any specific type of therapy for this condition and aware of the fact that rheumatic fever, like syphilis, smoulders for years, insidiously producing increasing destruction, I am thoroughly in agreement with the English investigators when they say that the only possible method of preventing this prolonged infection is to put these children to bed for a period of months, six months on an average, until all signs of activity have ceased. I had the opportunity of visiting some of the institutions the English have provided for their rheumatic children. They call them residence hospitals. I believe a better name would be convalescent homes or preventoriums. At Carshalton, a short distance out of London, is located Queen Mary's Residence Hospital, where about 350 rheumatic children are being provided with prolonged rest in bed in the best environment. The hospital is located in a beautiful garden spot in the country. It consists of a number of small units all built on one floor. The buildings are constructed so that the beds can be rolled out into the sunshine, when the sun shines in England. In cloudy weather ultraviolet therapy is provided by lamps. Nutrition is kept up by the best of food. The children are arranged according to age and stage of activity of the disease, giving a rather uniform group for teaching purposes. Each ward is a classroom presided over by a most efficient teacher. These children continue their school work even while they are flat in bed. They are kept in bed from one to three months until all signs of rheumatic activity have disappeared. They are then permitted to sit up a little more each day until they are finally out of bed and then spend a number of weeks in supervised outdoor activity. They do some gardening and are taken on walks of increasing distance. A number of these children are then transferred to a small convalescent home for a short stay at the seashore. Many of them go back to the schools for physically defective children, much like Dowling, and, if their condition permits, are finally transferred to their regular schools. This, to my mind, is an ideal régime for recent post-rheumatic children. I believe this type of treatment should be provided wherever there are enough rheumatic children, especially in a temperate climate like our own, where rheumatic fever is always present and where a large number of cases appear each year.

Of course, you will want to know immediately whether or not I can prove that this sort of convalescent treatment does help these children. Are they any better after they have been in bed from three to six months in such an institution? As yet there are no large collections of figures available. The oldest convalescent home for rheumatic children is probably not much over five years old. Dr. Thomson of Birmingham, who has been in charge of the Baskerville Convalescent Home since its origin five years ago, writes me that he has collected 500 cases of rheumatic children who have passed through Baskerville School but he does not see how it is possible to decide what the real value of such convalescent treatment is until a considerable period of years has elapsed. He hopes to review these 500 cases in another three or four years, when the children will all have mixed with the world on ordinary terms for at least ten years or more. However, he does state that "there is no doubt that the immediate results are very good."

Campbell and Warner in a recent article compared the results of treatment at the Carshalton Convalescent Home with those obtained in the group treated at home and as out-patients. Both groups were studied for at least a year in the out-patient department and the authors conclude as follows: "The number of relapses in the first three years was only half as many in the children who went to Carshalton as in those who did not. This is all the more striking when it is realized that originally they were more severe cases." I have also a letter from the English Ministry of Health in which they write as follows: "It will be observed that it is stated in the Annual Report of the Chief Medical Officer of the Ministry of Health that London is just completing new accommodations of 350 beds in addition to existing ones for the treatment of rheumatic troubles in children." The English investigators are agreed that convalescent care of rheumatic children is at present the only method of attempting to prevent rheumatic heart disease in children.

Considering the state of our present knowledge and aware of the fact that rheumatic fever is a prolonged insidious disease that slowly cripples the heart over a period of years, I am thoroughly in accord with the English opinion. McCullough of St. Louis wrote a short statement in a bulletin issued by the American Heart Association recently in which he recommends this sort of treatment. Another bulletin from the American Heart Association issued this week discusses the value of preventorium treatment of rheumatic disease. A number of convalescent homes have already been provided in this country and I am hoping that we will have one of our own during the next year. I believe these children are entitled to this kind of treatment; I do not believe that we should stand by doing nothing while we are waiting for some specific treatment which we all hope will be forthcoming in the very near future.

TUBERCULOSIS, A PUBLIC HEALTH PROBLEM*

H. A. Burns, M.D.
Superintendent, Minnesota State Sanatorium
Ah-Gwah-Ching, Minnesota

TUBERCULOSIS is a disease characterized by a specific etiology, a positive epidemiology, and an uncertain therapy. The tubercle bacillus bears a marked resemblance to other pathological organisms in that it is able to live in a favorable environment outside the human body for weeks and months and is resistent to direct sunlight for several hours and indirect sunlight for as many days without losing its virulence. It is able to withstand heat under all ordinary conditions as met in nature.

The epidemiology of tuberculosis depends upon the possibility of contact between the organism and a susceptible individual. Experience has taught us that the infection, once introduced, may remain a local unrecognized and unidentified lesion causing no symptoms and attracting no attention for weeks and months before the onset of prodromal symptoms or the arrival of the day of breakdown. Experience has taught us that this period of initial infection is the time to diagnose tuberculosis in the hope of curing the patient and saving a healthy body from chronic invalidism.

The epidemiology of tuberculosis is most concerned in the source of original contact with the positive sputum case. The more intimate the association with the open case in the community, the greater is the incidence of infection.

INCIDENCE OF INFECTION

The following investigators have reported various percentages of infection in different age periods and groups:

Armstrong[1] (Framingham): 15 per cent second year of life; 45.7 per cent from 6 to 7 years; 54 per cent from 7 to 15 years.

Lampson[6] (Minnesota): 2.5 per cent in non-tuberculous families; 22 to 33 per cent in tuberculous families; 67 to 100 per cent in families with open cases.

Slater[9] (Minnesota): 5 per cent in children without family history; 8 per cent in children with questionable history; 88 per cent in children with positive family history.

Leigh[7] (Texas): 82 per cent Mexican school children.

McCain[8] (South Carolina): 22.59 per cent school children.

Ferguson[4] (Canada): 93 per cent Indian school children; 54 per cent general school population.

Heimbeck,[5] in the study of 420 nurses, found that 220 showed negative reactions at the time of admission. Soon after being placed on tuberculosis service, they became positive reactors.

Heimbeck states, "As far as the rest of the nurses who originally gave a negative reaction to the Pirquet test are concerned, only one of the 1924 class, two of the 1925 class, and six of the class of 1926 still gave a negative reaction. It can now be stated as certain that in the course of one or two years, the reactions of practically all of those who formerly gave a negative reaction to the Pirquet test have become positive and about twenty per cent of them have contracted a tuberculous infection."

The school survey and epidemiological investigation of tuberculosis in infected communities have shown that a large percentage of uninfected young people annually leave their homes and go out into the world to earn a livelihood. These uninfected young men and women under present conditions must frequently and unconsciously come in contact with open cases of tuberculosis. The results of observation at this time indicate that the uninfected youth or adult upon becoming exposed is in danger of developing clinical tuberculosis.

The problem of resistance and allergy must be considered in relationship to the original exposure and to repeated exposure in this class of susceptible contacts. From an epidemiological point of view it does not matter greatly to which view concerning this question one adheres. For control purposes it is necessary to keep the uninfected and the infected non-clinical case from contact with the positive sputum carrier.

---

*Read before the Minnesota State Sanitary Conference, Saint Paul, December 8, 1930.

Both groups have been shown capable of developing parenchymal tuberculous lesions.

Epidemiology has demonstrated the occurrence, in communities, of areas heavily infected with tuberculosis. Such areas should receive special attention from those engaged in tuberculosis control.

Chadwick[2] says, "Different sections in the same city may show a wide variation in the percentage of reactors. It was found that in one city of 60,000 that the number of children reacting to the tuberculin test in different school districts varied from 11 per cent to 60 per cent."

Zimmerman[11] has found that the tuberculosis infection fluctuates from one year to another. Over a period of four years, it was found to vary from 58 to 77 per cent.

The migratory carrier is an ever present problem in tuberculosis control. The Minnesota State Board of Health[10] reports concerning this group of cases during the ten years 1920 to 1929:

1690 cases left Minnesota for residence elsewhere
1848 cases entered Minnesota and were examined in one clinic
638 cases came to Minnesota to reside
4396 reciprocal notifications in Minnesota during ten years time

It is essential in the control of any contagious disease to know where and when and under what conditions it occurs. Without these data epidemiology is helpless; with them, however, the most costly disease to both life and treasure resolves itself into a simple formula.

During the years 1918 to 1927, among 18,880 fatal cases in Minnesota 6,565 (34 per cent) were not reported as provided by law previous to the time of death. In 1929 there were 1,441 deaths, 547 (37 per cent) of which were first reported by death certificate.

During the five year period from 1925 to 1929, the forty-seven counties in Minnesota not supporting sanatoria reported 3,967 cases of tuberculosis to the State Board of Health; 937 (23 per cent) were reported by death certificate only.

The remaining forty counties supporting county sanatoria and containing over 65 per cent of the total population, reported 15,398 cases of tuberculosis of which 1,793 were reported by death certificate only.

Of the cases reported by death certificate only 27.9 per cent came from Hennepin, Ramsey, and St. Louis counties; 37.7 per cent from the thirty-seven remaining counties supporting sanatoria. Of cases reported by death certificates only, 34.3 per cent were from the forty-seven counties not supporting county sanatoria.

Table I
CASES REPORTED BY DEATH CERTIFICATE ONLY IN MINNESOTA

	Per cent
1925	26.38
1926	26.94
1927	34.45
1928	32.35
1929	38.02

It is not evident from these data that the county sanatoria are aiding materially in getting cases reported. However, the public sanatoria have not yet fully appreciated their duty to the communities they serve, since there is little if any attempt made to trace tuberculosis infection. The sanatorium is created by the community to reduce the incidence and control the spread of tuberculosis. The sanatorium must choose to become a part of the epidemiological control of tuberculosis, or it will become more and more an institution concentrating upon therapy.

If treatment is overemphasized and epidemiology neglected, the sanatorium cannot escape the criticism of practicing "State Medicine."

The cases reported and deaths occurring during 1923 to 1928 in age groups show an absence of the application of prevention most noticeable in the age group under five and less so from five to nineteen. The reporting of cases improves in the higher age level and is most complete at 65 and over, where it is of least value.

The majority of tuberculosis infections occur in the lower age groups; yet only a small number of cases are reported in this age group. The accompanying chart shows that under five years of age there were 734 cases and 493 deaths. From five to nineteen, there were 3,804 cases and 1,071 deaths, and from twenty to sixty-five and over, there were 18,546 cases reported and 8,306 deaths.

The industrial and reproductive ages contribute greatly to both case and death rate, yet the pre-industrial age is the period during which much of the exposure and infection occurs. One group should be protected against the other.

During this period up to thirty-five years when infection and allergy are being acquired, there were 5,275 deaths, with 4,559 deaths oc-

curring in the higher age levels. Concentration of effort to the end that all cases be reported promptly and that control measures be instituted effectively will result in the prompt identification of the infected among the younger age groups together with the prompt isolation of cases in the later ages, thus reducing the number of cases and deaths in the earlier ages. The effect of epidemiological control will be noticed first through the lowering of the case and death rate throughout the lower age level.

During the past five years twenty-five cases of hilum disease (first infection) were admitted to the Minnesota State Sanatorium from the fifty unorganized counties. While this futile attempt was being made to care for cases of juvenile tuberculosis, 1,937 deaths, in children and adults, actually occurred among the residents of these counties. Sixty-two teen age cases were admitted from these unorganized counties during this period.

To control tuberculosis we must not only gather our data, but we must apply the knowledge derived from them. With the physical equipment now available to fight tuberculosis, with the accumulated epidemiological knowledge waiting to be put into service it is possible to bring under control the easiest of all communicable diseases, pulmonary tuberculosis.

CONCLUSIONS

It is apparent that if our anti-tuberculosis work follows a progressive program, future effort must be largely devoted to the epidemiological study of tuberculosis.

The valuable information accumulated by the State Board of Health must not be allowed to lie dormant. The prompt application of knowledge now available will go far towards successful control. In fact the ultimate control of tuberculosis is dependent upon our opportunity to accumulate, to study, and to apply statistical and epidemiological data to the problem.

The sanatorium as a public institution must serve for purposes of control. To do so it must concentrate upon epidemiology rather than upon therapy.

A study of the data supplied by the State Board of Health would seem to indicate that the sanatorium, except for isolating the positive sputum case, has made no marked contribution towards the control of tuberculosis.

We must emphasize in the future more contact with the environment that is permitting tuberculous infection to spread, rather than more equipment for the clinical care of the one already broken if our objective is to control and our efforts are to end in a minimum case rate and a residual death rate.

It is not the periodic examination that is necessary in order to detect early tuberculosis but rather epidemiological investigations of exposed groups and communities that early infections may be identified, that gives a promise which commands our consideration today.

The public sanatorium must become a part of the epidemiology of tuberculosis. Effective coordination between these two activities will accomplish where either alone must fail.

OUR STATE INSTITUTIONS

THE FEEBLE MINDED, BLIND AND DEAF*

J. M. Murdoch, M.D., Superintendent Minnesota
School for Feeble Minded
Faribault, Minnesota

The Minnesota State Board of Control conducts eighteen State Institutions for the mentally ill (insane), the mentally defective (feeble minded), the epileptic blind, deaf, delinquent, tuberculous and crippled. The total population of these institutions is about 15,000.

The Journal of the American Medical Association in its hospital number, issued March 29, 1930, in tabulating the number of beds and patients in hospitals, reports as follows:

GENERAL HOSPITALS

	Number of Hospitals	Beds	Patients
Minnesota	164	10,796	7,080
United States	4,268	357,034	234,009

NERVOUS AND MENTAL HOSPITALS

	Number of Hospitals	Beds	Patients
Minnesota	15	10,627	10,281
United States	572	414,386	395,407

There are more patients in hospitals for mental and nervous disorders than in all the general and other special hospitals combined.

The hospitals for mental and nervous disorders, including the feeble minded and epileptic, are crowded to capacity, and their population is increasing at a rate much faster than the increase in the general population.

In the United States today, at least 1,000,000 people are social liabilities because of mental disorders. Seventy-five thousand people are walking the streets today who will be in institutions for mental patients within a year, and of these, 1,500 are in Minnesota, and will be seen by physicians of this State.

There are 67,000 feeble minded under training and treatment in institutions in the United States. Of these 2,050 are in the Minnesota School.

These statistical findings are conclusive evidence that our handicapped citizens constitute a tremendously important medical, social and economic problem.

THE FEEBLE MINDED

The Minnesota School for the Feeble Minded, situated in Faribault, was established in 1879. It has accommodations for 2,050, and is always filled to capacity. The institution, as its name implies, is primarily a school —a school for the training of children who, on account of mental defect, are unable to receive appropriate instruction in the public schools.

By the use of psychological test criteria, it is possible to select these children with a considerable degree of confidence and plan for their future training.

It is unjust to compel these handicapped children to compete intellecutally in schools designed for those who possess normal mental endowment.

Where the child is definitely feeble minded and cannot receive adequate care and supervision in the home, or where a special class is not available in the public schools, the child should be sent to the institutional school when six or seven years of age.

At present, far too many feeble minded children, particularly girls, are not sent to the institutional school until quite grown up, and then only after they have acquired anti-social habits, difficult or impossible of eradication. For these the possibility of successful social adjustment for life outside of the institution is materially lessened.

However, children sent to the institutional school, should be a selected group. This group should consist of those who exhibit symptoms of social maladjustment in which the environmental influences are difficult to modify, and are fostering the development of unfortunate personal reactions.

With an intelligence quotient above .50, where home conditions are satisfactory, and a special class in the public school is available, the child should not be sent to the institutional school unless he gives evidence of anti-social conduct which cannot be controlled at home. The extremely helpless child (with an intelligence quotient below .25) can frequently be cared for quite as well at home as in the institution.

On admission each child is given a thorough mental and physical examination.

In school he is assigned to tasks well within his capacity. Instruction is of practical type, proceeding at a speed commensurate with ability. Periods of study are short, with frequent intermissions for recreation. Industrial work predominates, as it is in manual training these children do best. Much individual attention is necessary, requiring instruction in small groups.

The task is fitted to the child, and not the child to the task. Girls are taught all branches of house work. Many become experts with the needle. Boys are trained for simple industrial work in the shop or on the farm.

Every pupil is given an opportunity to go as far in academic school work as his capacity permits. However, few go beyond the fourth grade. Good social and industrial habits are formed.

Pupils in the higher grades who have a mental development over eight years are trained for life outside of the institution. After appropriate training, many of these become stable in their habits and are successfully employed at manual labor on farms or in simple industrial operations.

Where the condition is due to hereditary defect, a sterilization operation is performed, after which the child may be returned to the home, or where home conditions are not satisfactory girls are sent to club houses, maintained by the State Board of Control. These club houses are home-like, attractively furnished, each caring for from twenty to twenty-five girls, who live under the supervision of a matron, going out to work by the day. These girls are self supporting, and after paying for board, clothing and other incidentals they are encouraged to deposit any surplus money they may earn in a savings account.

---

*This and the following articles compose a symposium on Our State Institutions, presented before the annual meeting of the Minnesota State Medical Association, Duluth, Minnesota, July 14, 1930.

Plans for the establishing of similar clubs for boys are being considered.

At present many of the higher grade boys are finding employment on farms. Sterilization has made it possible for many to be placed outside of the institution where this otherwise would not be considered.

For the lower grades, even after the training given at the school, few homes are able to give the constant supervision and the protection required. These remain in the institution where they live, happy and contented in their limited environment, at work and play with congenial companions of their own mental level, and supervised by attendants who appreciate their limitations.

As to the causes of mental defect, our records show that about one-half of those admitted have near relatives similarily afflicted. We have nine brothers and sisters from one family, and many family groups of three, four and five.

As to the other one-half, where there is no history of mental defect in the family, a large number are the end-results of infection, and trauma. Encephalitic and meningitic involvement may be complications of infectious diseases including those not primarily affecting the central nervous system. That encephalitis may be a complication of measles and other exanthemata has been conclusively demonstrated at autopsy. Microcephalus may follow the irradiation of the pregnant uterus. Obstetrical accidents, and accidents later in childhood, resulting in severe head trauma, make their contribution.

Syphilitic parentage frequently is antecedent to a low grade encephalitis resulting in feeble-mindedness.

Sterilization as carried on at the Minnesota School for the Feeble Minded is more than a eugenic measure.

Feeble minded persons do not make good parents, regardless of the mentality of their offspring. Sterilization is useful as a measure for insuring a better social adjustment and is of constructive value in the rehabilitation of the trained defective.

Under the parole plan, subjects deemed suitable for life outside of the institution are sent out on trial, remaining under the continuing supervision of the State Board of Control.

The Minnesota School for the Feeble Minded is always filled to capacity, and new cases are admitted as rapidly as possible from the waiting list of those committed by a Probate Court to the guardianship of the State Board of Control.

Before a feeble minded person can be admitted to the institution, he must first be committed as a feeble minded person to the guardianship of the State Board of Control.

THE BLIND

The Minnesota School for the Blind is maintained by the State, under the direction of the State Board of Control. The superintendent is Professor J. E. Vance.

The school is attractively located in a park on a high bluff, overlooking the city of Faribault. Its opportunities are free of charge to all blind persons in Minnesota between the ages of six and twenty-one, who are capable of profiting by instruction. Forms for making application for admission may be obtained by addressing the superintendent.

By a blind person is meant one who has not sufficient sight to receive satisfactory instruction in the public schools.

Eight years is the regular period of instruction, but at the expiration of that time an additional period of four or five years may be granted.

The work of the school is conducted in three departments, the literary, music and industrial.

There is very little formality for the admission of a pupil to the School for the Blind. After the first admission the child returns to the school year after year in the same way he would return to the public school, continuing in the school, year after year until he completes the course and leaves upon graduation.

The Literary Department, or school proper, has a primary course of four years, an intermediate course of four years, and a higher course of four or five years. The instruction includes kindergarten training and the branches usually pursued in the graded and high schools for normal pupils.

In the Music Department, instruction is given upon the piano, the pipe organ, the violin, and other orchestral instruments; in individual and class singing and in the theory and history of music.

In the Industrial Department the boys are taught piano tuning, and repair and adjustment of piano players, and broom making. Both boys and girls are taught weaving, chair-caning and various forms of manual training, including cabinet work, basketry, hand and machine sewing.

The graduates from the school are well equipped to become self-supporting citizens.

THE DEAF

The Minnesota School for the Deaf is maintained by the State, under the direction of the State Board of Control. The superintendent is Mr. Victor O. Skyberg.

This school is beautifully located in Faribault. The buildings are attractive in appearance and well equipped. Its facilities are free to all the deaf children within the State between the ages of seven and twenty. Forms for making application for admission may be obtained from the superintendent of the school.

This school, as is the school for the blind, is a part of the general educational system of the State. The purpose of the school is to give the deaf children, mental, moral, physical and industrial training, that will make of them useful and productive citizens. At the present time there are 275 pupils in attendance.

A deaf child allowed to grow up without an education is a most pitiful object and unhappy burden upon society. The same child given the education this school provides becomes a happy and useful citizen. The child should enter the school at the age of seven years. That the instruction and training given at this school are successful is borne out by the results obtained.

The graduates of this school are all, without exception, self-supporting citizens. They are found in eighty-five different occupations which cover the professional and commercial field, and the skilled occupations of industry.

The trained deaf person has a salable service.

No blind or deaf child should be permitted to grow up in this State without having the advantages freely provided at these most excellent schools.

OUR TUBERCULOSIS SANATORIA

Arnold Anderson, M.D.
Saint Paul

It is still not a pleasant duty to be called upon to make a diagnosis of pulmonary tuberculosis; for the doctor, as judge, must impose upon the patient a sentence of prolonged bed rest and a period of personal discipline. It is a sentence which carries with it the curtailment of most of the ordinary pleasures in life: a renouncing of physical activity: a period of self-denial. These sacrifices which appear so crushing in their application are the price that must be paid by the patient of today for a recovery from tuberculosis. In former days, however, the outlook was infinitely more forbidding. The physician making the diagnosis felt deply the helplessness of the situation, for he viewed tuberculosis as a slowly creeping, relentless and exacting disease which held death as its price. The sanatorium has done much to change this ghastly picture. With the advent of tuberculosis sanatoria, the physician has come more and more to realize the curability of consumption and so to imbue his patients with higher hopes and greater assurance.

It was while the sanatorium idea was still comparatively new that Minnesota received its first introduction to it. This came through the wisdom and foresight of a certain socially minded physician, Dr. H. Longstreet Taylor. To this man, more than any other single individual, must go the credit and glory for establishing our Minnesota system of tuberculosis sanatoria, a system which has met with nationwide comment and approval.

Many of you here today can recall the Minnesota legislative session of 1901 when an act was passed providing for the appointment of a commission to investigate the advisability of establishing a State Sanatorium for Consumptives. The Honorable S. R. Van Sant, then governor, appointed to this commission three physicians: Dr. J. L. Cemp, Dr. G. S. Wattam and Dr. H. L. Taylor. After many months of investigation and study, this commission reported in a very effective way to the 1903 legislature advising the establishment of a State Sanatorium at Walker, Minnesota. The advice was heeded with the result that in 1908 the doors of the first sanatorium in Minnesota for tuberculous patients were opened. The example of the state was soon followed by St. Louis County, which, acting under the authority granted by the 1909 legislature, established the first county sanatorium in our state. Otter Tail County followed suit and in 1913 completed its institution for the tuberculous. Following this, through the efforts of the State Advisory Commission headed by Dr. Taylor, the 1913 County Sanatorium Law was passed. Briefly stated, this law provided that to any county or group of counties erecting a tuberculosis sanatorium according to standards set by the Advisory Commission the state would lend its support to the extent of one-half the cost of the sanatorium, up to the sum of $50,000.00. The law further provided that the state would help in maintaining the institution by paying to it $5.00 per week for every resident free patient which it housed. This law proved to be a great boon, for soon after its passage one sanatorium after another made its appearance. At the present time, we have 14 county, 1 state, 2 federal and 3 private tuberculosis sanatoria in the state. Besides this, beds for special tuberculous patients are had in the following state institutions: University Hospital—12 beds; Rochester State Hospital—38 beds; St. Peter State Hospital—55 beds; Hastings State Asylum—3 beds; Colony of Epileptics, Cambridge—8 beds; Minnesota School for Feeble Minded—22 beds; Fergus Falls State Hospital—73 beds; State Prison—12 beds; Minnesota State Reformatory—7 beds. In all, we have a total of 2,616 beds for the care of our tuberculous patients.

Of late, it has been our endeavor to interest the non-sanatorium county in affiliating with an already existing institution. Forty of the 87 counties in the state are so affiliated. They have a convenient, necessary and valuable way to care for these patients and it is safe to say that these communities are the better served because of it.

I will be brief as to the method of operation of our county sanatoria. The Minnesota plan carries with it a check and double check system. Locally, the institution is governed by the sanatorium commission, whose function is to hire or discharge the superintendent and to approve of all bills and expenditures. Centrally, the various sanatoria are responsible to the State Board of Control (which in 1925 took over the duties of the Advisory Commission) for the operation of an institution which must measure up to certain set standards. Failure to do so gives the Board of Control authority to remove state aid to that sanatorium. In having both a local and central body interested in the welfare of the institution, there is given a certain stability and order to our system which other plans lack.

You are all acquainted with the ordinary functions of our sanatoria, as places of isolation for the infectious tuberculous patient and as institutions for the modern care and treatment of tuberculosis. It is necessary, however, to go further than that in combating a communicable disease. There is great need to give to the community which is served a true and proper understanding of an infectious disease. For that reason, we like to view our sanatoria as health educational centers which by newspaper articles and other ways try to instill into community life a better appreciation of health. During the past two years, short courses in tuberculosis have been held at many of our institutions in order to give to the busy medical practitioner the newer knowledge gained in the control of tuberculosis. These courses have served a valuable purpose.

They have brought the sanatorium and the private physician into closer contact. It has resulted in an exchange of ideas which has proved mutually beneficial.

I cannot close these brief remarks without extending to you a freer use of our sanatoria; a welcome to our many facilities. The institutions are a part of your community paid for and supported by your taxes, built and maintained to give you service and existing for the purpose of bettering community health. Our sanatorium system was born of the medical profession. It must be nourished by the same body in order to thrive and prosper until its work is done.

EPILEPTIC COLONY

D. E. McBroom, M.D.

Cambridge, Minnesota

It is not my intention to tell you anything about epilepsy, as this is a disease with which you are all thoroughly familiar, but will confine my few remarks to the methods in use, in admitting and discharging these patients to and from your State Institution.

The path of the epileptic is a very turbulent one, and has so many ramifications that the different types of patients we encounter in this field might fit into any of the classifications of mental diseases or sociology. As we all know, epilepsy is a progressive, degenerative process, so that the majority of epileptic patients sooner or later degenerate sufficiently to become feeble minded. It is also true that a very large percentage of epileptics are afflicted with psychosis of some kind which makes them follow the path of the insane, and, owing to the inferiority complex which is nearly always present, many of them become delinquent. Then, due to their instability, practically all are dependents. Thus you see the care of the epileptic covers a very broad scope.

The State of Minnesota has for many, many years taken care of the epileptic patients in the School for the Feeble Minded at Faribault. Owing to the crowded conditions there and realizing that the high grade epileptic and the feeble minded patients were more or less incompatible, the State Board of Control saw fit to establish a separate Colony for Epileptics in 1925. This was located at Cambridge, where we have all new bulidings, the latest type of construction and particularly well adapted to the handling of this type of patients, and, while new, the institution has made remarkable progress since it was organized.

Minnesota has no separate law governing the commitment of the epileptic patient. At the present time we have two separate and distinct procedures which are followed in this state. The first and most efficient and the one which covers the vast majority of cases is that of commitment of the epileptic to the custody of the State Board of Control as feeble minded. By this method the family, relatives, or anyone who is a resident of the state may file complaint and it becomes the duty of the Judge of the Probate Court to set a time for the hearing. At this hearing, the County Attorney represents the patient and it is his duty to see that the patient is given a fair trial or hearing. Two regularly licensed physicians are called who serve as examiners and assist the Judge in making his decision. If the patient is found to be feeble minded to the extent of having an intelligence quotient of .70 or below, he is then committed by the Probate Judge to the custody of the State Board of Control. The State Board of Control then assigns this patient to any one of the institutions under their jurisdiction, which seems best adapted to the needs of this particular patient, and his name is placed upon the waiting list and is usually called for in the regular order of commitment, although there may be times when the Board of Control may use its discretion and advance a case a little ahead of his turn; but this procedure is applied only under very extenuating circumstances. The other method of admission to the Colony is that of the voluntary patient. In these cases we insist that the I. Q. be above .70 with a clean cut diagnosis of epilepsy. Under these conditions an epileptic patient may place an application for voluntary admission, signing a blank to abide by all the rules, laws and regulations of the State Board of Control and the institution, and his name is then placed on the waiting list to be called in his turn. The State Board of Control through the Children's Bureau has the handling of the waiting list and takes care of these patients as rapidly as possible, but no preference is given to the voluntary patient over those committed by court. The patients who have been committed to the guardianship of the State Board of Control are held in the institution until discharged or paroled by the State Board of Control. There is no sentence given, nor is a patient discharged by reaching any certain age limit, and of course any discharges because of a cure are practically nil, so that the vast majority of epileptics are assigned to the institution for the rest of their lives, unless they have a cessation of spasms for a number of years with a minimum amount of degeneration, when they may be released by order of the Board of Control. In the case of the voluntary patient, the release is an entirely different procedure. The voluntary patient has only to make written request for his release to the Superintendent of the institution and we have no way whereby we can prevent him from leaving. However, we request that he give us three days' written notice so that he will not be walking out of the institution when he is momentarily upset because of recent spasms or some other irritating circumstances. Very few patients qualify for voluntary admission, as nearly every epileptic who has had seizures for any prolonged time has degenerated sufficiently to place him in the court commitment class.

To summarize, I wish to say that the matter of all admissions and dismissals of all court cases lies entirely with the Board of Control and that only the question of discharge of the voluntary patients is left to the judgment of the superintendent. Upon admission to the institution all patients are treated alike regardless of the method of commitment. No special favors are granted to the voluntary patients although many of them arrive at the institution with this idea firmly imbedded in their minds.

In closing, I wish to state that the Minnesota Colony for Epileptics is located in the Village of Cambridge on Highway No. 5, forty miles north of Minneapolis, and we would be very glad indeed to have any and every member of the association visit the institution at any time they may see fit and see what your State is doing for this group of unfortunates.

GILLETTE STATE HOSPITAL FOR CRIPPLED AND DEFORMED CHILDREN*

Carl C. Chatterton, M.D.
Saint Paul

The care of the maimed, crippled and deformed has been a social problem since the beginning of time. Early laws before Christ regulating the care of crippled children are examples of extreme cruelty. In Rome, by law, the father of a crippled child could dispose of the child as he thought best. The Spartan mother when her child was born a cripple knew he would not become a good soldier, so she destroyed him.

About 600 A. D. cripples were tolerated in Italy principally because they were used for amusement as court jesters and objects of charity. Deformed and crippled children were used as a means of obtaining money, and if they were not deformed enough the parent or guardian saw to it that his charge was so deformed that he would make a pitiful sight and in that way secure money by begging.

Custodial or asylum care was given in England about 1600 and was established by Queen Elizabeth.

The first real school or training for crippled children was started nearly three hundred years later by Father John Nepimak in Munich. His school was the first to combine care and industrial instruction. In 1872 the first real industrial school was established by Pastor Hans Knutsen in Sweden.

In the United States, the care of crippled children is comparatively new. In 1844 the first American Home for the care of crippled children was established in Philadelphia. The first orthopedic hospital was established in New York City in 1863. In 1866 the second orthopedic hospital was established in New York. The first school for crippled children in the United States began in Boston in 1893.

The first legislation by any state in the United States for the care of their crippled children was in Minnesota in 1897.[1]

The exact date in the minds of those interested in the founding of a hospital for indigent, crippled and deformed children perhaps will never be known. The first records of the need of such an institution in this State are found in the proceedings of the Fifth and Sixth Minnesota Conference of Charities and Corrections.[2] In the year 1896 Jessie Haskins, a slender, crippled girl, read a paper before that body on the need of a state institution for the care of crippled and deformed children. The following year Dr. Arthur J. Gillette appeared before that body with a paper, The Duty of the State to Its Crippled and Deformed Children. This same year Jessie Haskins went before the State Legislature begging for the establishment of a state hospital and school in which other crippled children like herself, whose parents were too poor to pay for treatment, might be cared for and educated. Her plea brought action, largely because it was backed by an offer of free medical treatment and surgical care for all indigent children who might come. The offer of free service was made by Dr. Arthur J. Gillette, and the same year a bill was introduced and passed by the Minnesota Legislature providing a small sum for those who might come. Hasting H. Hart, then Secretary of the State Board of Charities and Correction, and later of the Russell Sage Foundation, gave his warm approval to the project.

The bill was not passed without effort, because at that time there was no such state institution or hospital for the care of indigent, crippled and deformed children, nor was there a law in the United States that could be used as a precedent, and the State Legislature was not anxious to take up with a new and untried institution or system.

The bill had but one object in view and that was the care, relief, cure and education of the poor, crippled children of Minnesota who, if not already so, would eventually become wards of the State. That the children would receive medical and surgical care without cost to the State was a surprise to the general State Legislature. On April 23, 1897, a law to provide for the care and treatment of indigent, crippled and deformed children was approved. The Board of Regents of the University of Minnesota was given power to act and $5,000.00 per year for the next two years was appropriated. The City and County Hospital, St. Paul, Minnesota, was the first home and gave a ward exclusively for the care of these children at a rate so low that it was possible in the first two years of the institution's existence to care for eighty children.[3] After the first two years, appropriations came easily and work increased so rapidly that the ward became filled and the necessity of a separate building became apparent. Grounds and a building adjoining the City and County Hospital were used and later given to the State by Ramsey County and the City of St. Paul.

In the year 1907, the City of St. Paul, Commercial Club, Business League, certain citizens, Mayor Smith, Senator W. W. Dunn, Dr. Robert Earl, Dr. Arthur J. Gillette and others gave the State twenty-three acres and $5,000.00 for cottages and improvements in the municipal Phalen Park where the Hospital now stands.

---

*Moving pictures were shown of the various activities, school rooms, social hours, recreation, operating rooms, class training and views about the grounds and hospital. These pictures of the various activities of the institution are available to clubs, medical societies, lay-gatherings without cost.

In this year the Board of Regents of the University of Minnesota asked release from control of the institution and the State Board of Control assumed charge.

In 1909, $55,000.00 was appropriated for the construction of a sanitarium at Phalen Park. In 1913, $60,000.00 more was appropriated for an addition to the sanitarium and in that year property of the State at the City and County Hospital was given back to the City of St. Paul and County of Ramsey and all the children were transferred to their present home at Phalen Park, St. Paul, Minnesota.

Since 1913 two large wings have been added to the institution. Gifts of a swimming pool and sun rooms are notable and worthy additions for treatment. The Michael Dowling Memorial Hall, a gift of the bankers and editors of the State, brings the present value of the entire institution over one-half million of dollars.

The present capacity is two hundred and fifty beds, requiring a personnel of one hundred and twenty-five to maintain the care of children. Forty medical men of St. Paul donate their services to carry on the medical and surgical service.

The institution as well as carrying on medical and surgical service endeavors also to give educational advantages to its inmates, and training is continuous the year around. Vocational training both in the institution and in nearby institutions is used as far as possible. Trades, dressmaking, arts, music, domestic science, are available to those who wish and need such service.

The institution is also used to advance medical knowledge. Three resident physicians are in attendance. Senior students from the University of Minnesota spend thirty hours at the institution for lectures and demonstrations. A training school for nurses for both undergraduate and postgraduate students is maintained.

HOSPITALS FOR THE INSANE

Arthur F. Kilbourne, M.D.
Rochester, Minnesota

Minnesota was admitted to statehood in 1858.

The first of any provision for the care of its insane was in 1863 when fifty-five patients were sent to the Iowa hospital at Mt. Pleasant and some seven to St. Vincent's retreat in St. Louis. In 1866 the first hospital was opened in St. Peter, Dr. Shantz, the first superintendent, stating in his first report that he found "an old dilapidated hotel undergoing repairs" used as a temporary hospital. This was soon overcrowded with its 100 patients but some patients brought from a distance of 100 miles or more in an open wagon were crowded in with the rest rather than have them undergo the fatigue and exposure of the return trip home.

Dr. Shantz died while the permanent hospital was only outlined by its basement walls. He was succeeded by Dr. C. K. Bartlett and in 1869 the first ward in the permanent hospital was ready for patients. Dr. Bartlett was superintendent for twenty-four years, his successors being Dr. Harry A. Thomlinson, Dr. Robert M. Phelps, and Dr. George H. Freeman.

The Rochester State Hospital, originally intended for an inebriate hospital, was turned over to the Board of Trustees and opened in 1879. Dr. Jacob E. Bowers, superintendent till 1889, was succeeded by the writer.

The Fergus Falls hospital opened in 1892 as a Homeopathic hospital, remained as such till recently, when that medical distinction was dropped. Dr. Alonzo B. Williamson, the first superintendent, after two years service was succeeded by Geo. O. Welch, who, after an incumbency of thirty-six years, was succeeded by Dr. W. L. Patterson.

More room being needed, the asylums at Anoka and Hastings were opened in 1902 and the Willmar Hospital for Inebriates in 1912, but in 1917 transferred to the care of the insane, reserving a ward for inebriates.
